THE EARLY DIAGNOSIS OF SYPHILIS

A CORRELATION OF CLINICAL AND LABORATORY METHODS

JOSEPH V. KLAUDER, M.D. (PHILADELPHIA)
Major, M. C., U. S. Army
CAMP UPTON, YAPHANK, N. Y.

This paper is an analysis of 115 cases of genital chancres showing the correlation of the three methods at our disposal for making an early diagnosis of syphilis: dark-field examination, Wassermann reaction, and clinical evidence. The laboratory diagnosis alone of syphilis presents pitfalls. The dark-field examination is of paramount importance in the early diagnosis of an untreated chancre, but its usefulness is greatly lessened as the majority of genital lesions have been treated locally before the dark-field apparatus is resorted to.

The Wassermann reaction is indispensable in syphilis, but in later stages than the initial lesion. This reaction is most important in the differentiation of pathologic conditions simulating subsequent syphilitic lesions. A positive Wassermann reaction is the serologic expression of the generalization of the disease.

If a chancre is seen while the Wassermann reaction is not yet positive, it is not necessary to await its appearance. To await its appearance as corroborative diagnostic evidence is much like the obsolete procedure of awaiting the appearance of the secondary eruption. On the other hand, reliance on clinical evidence alone is insufficient, since chancres vary greatly in their clinical manifestations. Indeed, some chancres may be so atypical that reliance on laboratory tests becomes imperative in order to make a correct diagnosis. Although it is not possible to diagnose early all cases of genital chancres by any of the three methods, the proper correlation of these methods promulgates differential diagnosis of genital lesions.

The importance of the early institution of treatment in the cure of syphilis places the burden of proof on the physician who classes any genital lesion as nonsyphilitic. This diagnosis should not be made until all three diagnostic methods are negative.

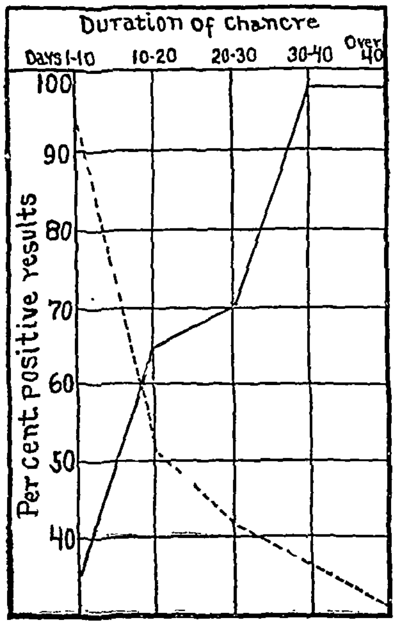

Fig. 1.—Comparison of Wassermann reaction and dark-field examination: solid line, positive Wassermann reaction; broken line, positive dark-field examination.

DARK-FIELD EXAMINATION

In an untreated and uninfected genital lesion, the absence of *Spirochaeta pallida* under the dark field is presumptive proof that the sore is not a chancre. A single negative finding, however, should never be taken as conclusive evidence, and the suspected lesion should *be reexamined at daily intervals. Unless the local condition* demands treatment, the genital lesion should be dressed only with physiologic sodium chlorid solution, boric solution, or simply warm water. No antiseptic treatment should be instituted until the diagnosis is established beyond a doubt. This is especially important because local treatment with a spirocheticidal drug greatly decreases the percentage of positive findings. The commonly used spirocheticidal drugs for local application are silver nitrate, mercury, iodin, copper sulphate, and iodoform. I have observed that spirochetes become very scanty on the surface of the chancre after one application of silver nitrate, which is the most powerful spirocheticide. The dark-field examination became negative almost universally after one application, although it was found that discontinuance of its use allowed a reappearance of the spirochetes on the surface. Two daily applications of calomel powder also caused the spirochetes to disappear from the secretion of the chancre. Here again they reappear if its use is discontinued. Daily rubs with 1 dram of unguentum hydrargyri are required for at least one week before the dark field becomes negative. It may be mentioned here that a single injection of arsphenamin usually causes spirochetes to disappear from the secretion of chancres within from six to eight hours. Infection of a chancre with pyogenic organisms may sometimes cause the spirochetes to disappear from the surface of the chancre, or reduce their number so that they can be demonstrated only with difficulty.

In previously treated chancres, the serum from the deepest part of the sore should always be examined, as it is unlikely that spirochetes will be found near the surface. When the dark-field examination is negative, the application of alcohol to the surface of a chancre may be of service by dilating the lymphatics and so bringing spirochetes to the surface of the lesion.

In Table 1 is shown the result of dark-field examination of 115 cases of genital chancres made at one to more than forty days after the first appearance of the sore. In thirty-three chancres examined within ten days of their appearance, the dark field was positive in thirty-one cases, or 93.9 per cent. In seventeen chancres examined *within from ten to twenty days* of their appearance, the dark field was positive in nine cases, or 52.9 per cent. In twenty chancres examined within from twenty to thirty days of their appearance, the dark field was positive in ten cases, or 50 per cent. In five chancres examined *within from thirty to forty* days of their appearance, the dark field was positive in three cases, or 60 per cent. The small number of cases in the last series probably explains the high percentage. In forty chancres examined after forty days of their appearance, the dark field was positive in twelve cases, or 30 per cent. The incidence of positive dark-field examinations became less in proportion to the duration of the chancre. Of the 115 chancres with an average duration of 33.4 days, sixty-five, or 57 per cent., were positive. This low percentage may in part be due to the fact that 66 per cent. of the chancres in this series had received local treatment previous to the time they were first seen. An added factor is the long average duration, as the longer the duration of the chancre, the more likely it is that its surface will heal. Furthermore, the possibility of a phimosis developing is greater. The sore is also more likely to have had local treatment, and finally pyogenic infection is more likely to be present.

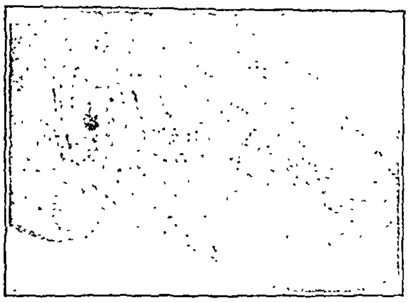

Fig. 2.—Abrasive chancre shaft: incubation, one month; duration, two days; self treated with iodin; dark field ++; Wassermann reaction —.

An added pitfall in absolute reliance on the use of the dark-field examination is apparent when it is noted that in 25.1 per cent. of the chancres in this series it was not possible to examine for spirochetes because the chancre was concealed beneath an inflamed or adherent foreskin, or the chancre's surface was entirely healed.

THE WASSERMANN REACTION

The value of the Wassermann reaction as an aid to the early diagnosis of syphilis is in proportion to the duration of the chancre. At the time of the first appearance of the sore, this reaction is invariably negative. The percentage of positive reactions gradually increases with the duration of the sore, until a short period before the appearance of the secondary eruption it becomes positive in 100 per cent. Therefore, in the early period of primary syphilis this reaction is not a very valuable diagnostic aid; in the later period, however, the reaction is of considerable diagnostic value. From an examination of Table 2 it is seen that within the first ten days of the appearance of the chancre, the Wassermann reaction was positive in only twelve of thirty-three cases, or 36 per cent. In seventeen cases from ten to twenty days after the appearance of the chancre, the Wassermann reaction was positive in eleven, or 64 per cent. In from twenty to thirty days the Wassermann reaction was positive in fourteen out of twenty cases, or 70 per cent. In the five cases from thirty to forty days after the onset of the sore, the Wassermann reaction was positive in all. In the forty cases existing over forty days, the reaction was positive in all. The average percentage of positive results obtained was 74.

TABLE 1.—DARK-FIELD EXAMINATION OF ONE HUNDRED AND FIFTEEN CHANCRES

TABLE 2.—THE WASSERMANN REACTION IN ONE HUNDRED AND FIFTEEN CASES OF PRIMARY SYPHILIS *

Duration of Chancre in Days	Number of Cases	Wassermann Reaction		Positive Wassermann Percentage
		Positive	Negative	
1-10	33	12	21	36.0
10-20	17	11	6	64.7
20-30	20	14	6	70.0
30-40	5	5	0	100.0
Over 40	40	40	0	100.0
Total cases......	115	82	33	74.1

* The Wassermann tests in this series were performed by Capt. Malcolm McBurney, M. C., U. S. Army, base hospital, Camp Upton, according to this technic: A one-quarter Wassermann was performed. The total volume in each test tube was 1.25 c.c., or one fourth of the amount used by Wassermann in the original test. Diagnostic tube: 0.05 c.c. of serum; one fourth of the anticomplementary dose of antigen; complement was titrated at every test; two units of complement were used with the alcoholic antigen and three units with the cholesterolized antigen; physiologic sodium chlorid solution was added up to 1.25 c.c. Control tube: 0.1 c.c. serum; complement according to titration; physiologic sodium chlorid solution was added up to 1.25 c.c.; incubated two hours on ice and one-half hour in the hot water bath at 37 C. Twenty-five hundredths c.c. of sheep's cells and 0.1 c.c. of amboceptor were added to each tube; these were incubated until controls were clear. One-tenth c.c. of amboceptor constituted two *hemolytic units.* The dilution of antigen used was 1:20.

It is not desirable that the Wassermann reaction be employed as a diagnostic aid in primary syphilis, because the appearance of this test probably means that a general invasion of the spirochetes has taken place. In experimental syphilis this is definitely known to be so. The disease should be diagnosed and treatment instituted before this invasion occurs. The time of appearance of a positive Wassermann reaction in primary syphilis is variable. Hence this test should be made in all cases of chancres.

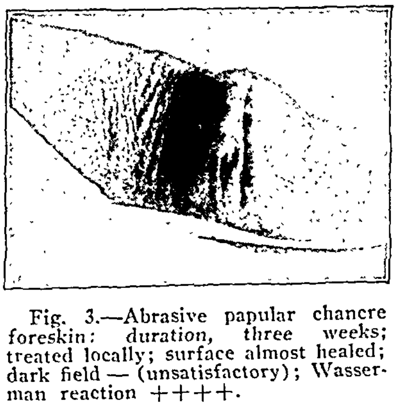

Fig. 3.—Abrasive papular chancre foreskin: duration, three weeks; treated locally; surface almost healed; dark field — (unsatisfactory); Wasserman reaction ++++.

The sooner the chancre is examined the more likely it is that the dark-field examination will be positive and the less likely that the Wassermann reaction will be positive. (Fig. 1). *Later, however, the converse is true.*

GENERAL CLINICAL FEATURES OF A CHANCRE

Before describing the clinical features that differentiate the chancre from other genital sores, it seems advisable to emphasize the need of a new terminology of nonsyphilitic infections. The vital importance of any genital lesion is the possibility of its being syphilitic. Once the lesion is proved to be nonsyphilitic it becomes relatively unimportant. Therefore the more general term of "nonsyphilitic" genital lesion is advocated lieu of the loosely applied term "soft chancre" or "chancroid." Venereal sores on the genitalia can be divided into three classes: (1) syphilitic, due to *Spirochaeta pallida;* (2) chancroidal, due to the Ducrey bacillus; (3) pyogenic, due to other organisms. A syphilitic genital lesion is a definite one due to a specific etiologic factor, *Spirochaeta pallida.* Thus diagnosis can be definitely made by demonstrating this organism by dark-field examination. Chancroidal infection is also specific, and is due to the bacillus of Ducrey. A genital sore should not be diagnosed as chancroid unless this bacillus can be demonstrated. This is possible only early in the existence of the sore. The other infectious genital sores may be due to various organisms that have not as yet been isolated. Differential diagnosis is often difficult and sometimes impossible if two or more of the above genital sores exist at the same time.

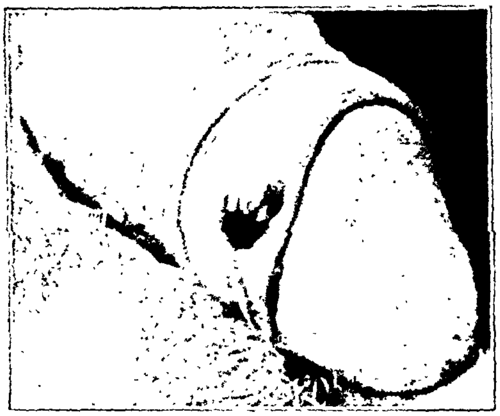

Fig. 4.—Abrasive indurated chancre foreskin: incubation, sixty days; duration, six days; untreated locally; dark field + + +; Wassermann reaction —. The surface was covered with a crust and sharply marginated; slight underlying induration.

Of late years in the diagnosis of syphilis the appearance of the chancre has been neglected. With the advance of laboratory methods of diagnosis there has been an unfortunate tendency to depend more on laboratory evidence than on clinical manifestation.

The nomenclature of the different types of chancres is as various as the textbooks on venereal diseases. The nomenclature employed in this paper is an attempt to clarify this subject.

GENERAL CONSIDERATIONS

Incubation Period.—Three weeks is usually given for the incubation period of a chancre. Our experience has led us to believe that in the majority of cases the incubation is between fourteen and forty-two days, with an average of about thirty-three days. The accepted minimum period is ten days and the maximum ninety days.

Multiplicity of the Sore.—The presence of more than one sore is no strong evidence against the lesion's being a chancre. Most textbooks give the impression that a chancre is rarely multiple. By an examination of Table 3, it is seen that of 121 chancres, twenty-one, or 17.3 per cent., were multiple.

Autoinfection.—A chancre is autoinoculable.[1] In man as well as experimentally in animals a second chancre can be produced by reinoculation from the original chancre. This possibility decreases in proportion to the duration of the infection.

Floor of Chancre.—The floor has the redness of raw beef. There is a considerable amount of serous secretion present. This liberal secretion is a very valuable diagnostic sign. This secretion may dry into a crust which, when removed, discloses the beefy floor. If pyogenic infection occurs, either an ulcer (Figs. 6 and 7) is formed or a membrane results (Fig. 5) and covers the surface of the sore. This membrane is usually "cream green" in color. The floor may remain abrased or it may become closed. This may occur spontaneously or more likely as a result of local treatment.

TABLE 3.—LOCATION OF LESIONS

Location of the Chancre	Number of Cases
Prepuce	55
Sulcus	20
Shaft	15
Glans	9
Frenum	4
Urethra	2
Concealed (phimosis)	16
Total	121
Mixed infection (chancroid and chancre)	3
Multiple chancres	21

Edge of Chancre.—The edge is usually flat and sharply demarcated from the surrounding tissues (Fig. 4). This is an important clinical feature. In another type of the lesion the slightly elevated border may slope toward the eroded center and into the normal tissue. As a result, usually of pyogenic infection, the edge may be raised above the surface of the sore (Fig. 7).

Area Surrounding Chancre.—Usually the tissue surrounding the chancre is normal (Fig. 4). In the event of secondary pyogenic infection, a small zone of inflammation may surround the edge (Fig. 5).

Induration.—When induration is present, it is valuable evidence of syphilis; but its absence does not exclude syphilis. This feature of a chancre is variable. The induration may appear early in the primary stage or late. The older the lesion, the more likely is the induration to be marked. The degree depends in a large measure on the location of the chancre. As the result of pyogenic infection, induration may become less or even disappear entirely.

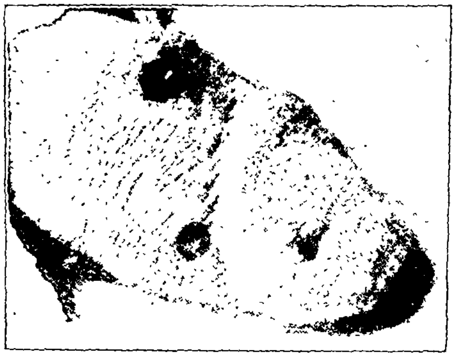

Fig. 5.—Infected abrasive chancre (multiple): incubation, six weeks; treated locally; duration, three weeks; dark field + +; Wassermann reaction + + + +. The floor was covered with a membrane "cream green" in color; the edges were on the level with the surrounding tissue; an area of inflammation surrounded the lesion; induration was absent.

Noninflammatory Edema.—When present, this edema is a valuable aid in diagnosis. It may involve the area surrounding the chancre, or the whole prepuce (Figs. 11 and 12). The skin is of a dull livid red or bluish tint. It feels tough and rubbery. The edema accompanying gonorrhea or a nonsyphilitic septic sore is softer when palpated and duller in color.

---

[1] Klauder, J. V.: Superinfection in Syphilis, J. Cut. Dis. **36**: 515 (Nov.) 1918.

Adenopathy.—The majority of adult males have some enlargement of the superficial lymph nodes. Friedlander,[2] in an examination of definitely nonsyphilitic cases, found in 85 per cent. a bilateral inguinal enlargement. Moreover, it may be impossible to distinguish syphilitic enlargement of the inguinal nodes from an enlargement caused by any other venereal diseases. However, the presence of enlarged inguinal lymph nodes, followed by a general enlargement of the lymphatic nodes, is characteristic of syphilis. In about 5 per cent. of cases of primary syphilis there is no palpable change in the lymphatic nodes. In the presence of secondary pyogenic infection, however, it is common to find a suppurative adenitis.

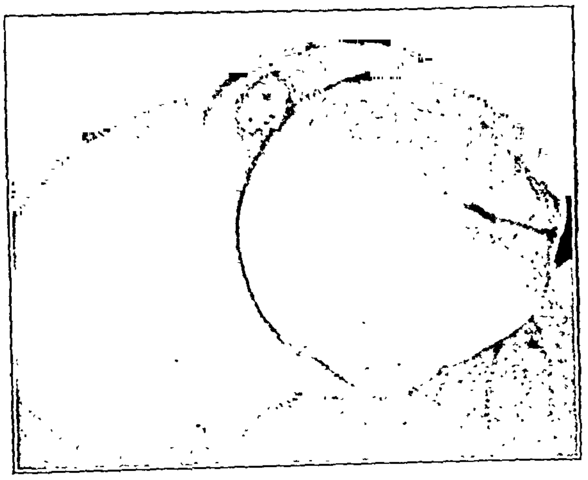

Fig. 6.—Ulcerated chancre foreskin (early): duration, three days; untreated locally; dark field ++; Wassermann reaction, alcoholic antigen —; cholesterized antigen ++++. The floor was ulcerative and dirty gray; the surrounding area of inflammation is shown in the illustration as a dark area; there was no induration; a localized area of edema surrounded the sore.

A nonsyphilitic genital lesion may be differentiated from a chancre. These sores start as a superficial ulcer and later become deep, or they may start as a pustule which breaks down and forms an ulcer. Such ulcers have gnawed, undermined edges. The floor is of a dirty gray, pitted and worm eaten in appearance. Later an area of inflammation surrounds the sore. Later the contour becomes irregular because, while one part of the ulcer tends to heal, the other invades the normal tissue. These nonsyphilitic sores are painful, bleed easily, and do not secrete serum so plentifully as do chancres.

The earliest clinical appearance of a genital chancre is a minute, sharply rounded, hyperemic area, which after a very short period becomes a superficial abrasion. This type of chancre is called the abrasive chancre (Fig. 2). It is usually seen only early, and is the first appreciable evidence of syphilitic infection. On account of the insignificant appearance of the sore it is most frequently undiagnosed. The surface is round, about 0.5 cm. or less in diameter, sharply marginated, smooth and polished. It appears exactly like an abrasion or excoriation because of shedding of the uppermost epithelial layer. The abrasive area enlarges and these changes take place: A secondary infection of its surface changes the sore into an ulcerative chancre (Figs. 6 and 7) or, if induration is present or subsequently develops, into an ulcerative, indurative chancre (Fig. 10). The ulcerative, nonindurative, orbicular chancre[3] (Fig. 8) is another type of ulcerative chancre. It is an atypical and rare chancre, occurring as a circular ulceration about the size of a penny; the floor is bright red with raised edges. Induration is notably absent. The characteristic beef-red floor suggested to Taylor the name "beefsteak" chancre. Infection of the surface of the chancre without ulceration is called infected abrasive (Fig. 5). If induration raises the sore above the level of the surrounding tissue, the surface remaining open, we have an abrasive papular chancre (Fig. 3). If the surface becomes closed, however, the sore is simply called a papular chancre. If induration appears below the level of the surrounding parts, an abrasive indurative chancre is formed (Fig. 9). A sore in which the induration spreads beneath and beyond its surface forming a thin disklike mass is called a parchment chancre.[4]

LOCATION OF GENITAL CHANCRES

The form of a genital chancre depends considerably on its location. The cellular reaction to the spirochete is modified by the tissue and the blood supply at the site of infection. The form of a chancre is also modified by extraneous factors, such as friction and infection. These in turn depend much on the location of the sore.

CHANCRE OF THE SHAFT

The majority of all sores seen on the shaft of the penis are syphilitic. The most commonly seen chancres in this location are abrasive, abrasive papular, and abrasive indurative types. In addition, the ulcerative nonindurative, orbicular chancre is usually seen only in this region. Chancres of the shaft, with the exception of the last type, become indurated early. Infection at this location is the exception.

CHANCRES OF THE PREPUCE

The roll of the prepuce just behind the corona, as is shown in Table 3, is the most frequent site not only for chancres but also for nonsyphilitic sores. There is no type of chancr characteristic for thi location. The frequently unclean stat of the prepuce, the absence of air, and th presence of moistur predispose to an earl infection. Hence clinical diagnosis ma be difficult (Figs. and 7). Induration i more likely to be present in chancres of th prepuce than in an other region of th penis. Induration i this location is mor easily estimated, as retraction of the prepuce pro duces a very characteristic appearance—the whol lesion flicks over like a plate turning on its edge. A the result of multiple chancres, induration may involv

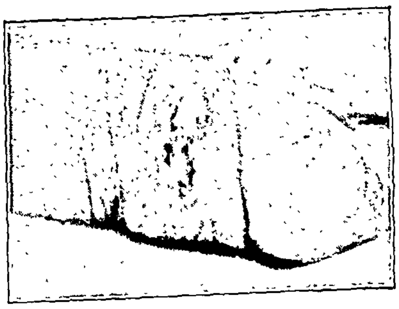

Fig. 7.—Ulcerative chancre foreskin (late): duration, fourteen days; untreated locally; dark field after many examinations was +; Wassermann reaction ++++. This sore was probably the result of pyogenic infection of an abrasive chancre; the floor was suppurative; at the center of the sore the edges were raised; slight induration was present.

---

[2] Friedlander, D. J.: J. Cut. Dis. 30: 14 (Jan.) 1912.

[3] Pictures of this unusual type of chancre are shown in Powe and Murphy's System of Syphilis, Taylor's Genito-Urinary and Venere Diseases, and McDonagh's Biology and Treatment of Venereal Di eases. In the latter volume an excellent description of this type chancre is given.

[4] The so-called hunterian chancre refers not to any particular typ of chancre but to the character of induration. Such induration commonly seen in a chancre of the sulcus (Fig. 10).

the entire circumference of the penis behind the corona, producing what is known as "collar" induration. Here, as elsewhere, the only evidence of a chancre may be a cartilage-like mass under the intact skin—the papular chancre.

CHANCRES OF THE SULCUS

There are two types of ulcerative, indurative chancres most frequently seen in this location. In one type there is a small area of ulceration on the floor of the sulcus surrounded by a rounded area of induration which extends farther and is more marked on the preputial side than on that of the glans. This induration extends only slightly beyond the corona. This crescentic form of induration produces the characteristic "swallow's nest" appearance. In the other type the induration and the ulceration are often so extensive as to involve the entire side of the sulcus (Fig. 10). The sore is inflammatory and painful. The surface may be covered with a "cream green" membrane, and there is usually present a foul-smelling secretion. Some induration is almost always present in chancres of the sulcus. This induration is usually of a cartilaginous nature and is whitish, because of the fibrous tissue which constricts the blood vessels. When the prepuce is retracted, the sore springs suddenly into view in a typical manner.

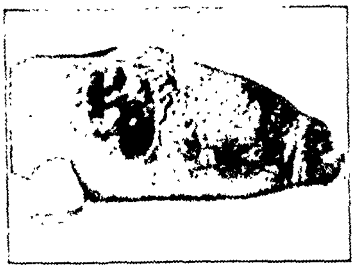

Fig. 8.—Ulcerative nonindurated orbicular chancre, treated locally with tincture of iodin; secondary eruption on body; dark field —; Wassermann reaction ++++. The floor was noninfected, beef red in color; the edges were raised; induration was absent.

CHANCRE OF THE GLANS

Two types of chancres are seen on the glans. One type is an abrasive chancre seen as a perfectly circular and sharply demarcated erosion (Fig. 9). The edges are flat and flush with the surrounding parts. Occasionally, however, the surface may be slightly below the level of the surrounding tissue. Early induration is absent; later, however, it is slight but is never marked. The second type of chancre is the abrasive papular, and is seen on the anterior part of the glans surrounding the meatus. This type is sharply circumscribed and slightly raised above the surrounding tissue. It appears as though the sore were stuck on the glans and then flattened out. The surface is usually crustaceous, and when the crust is removed the floor is bright red. This sore is more indurated than the first type.

CHANCRE OF THE FRENUM

The chancre may involve the base of the frenum or the entire frenum. Chancres of the base, when seen early, appear as abrasive, circular areas. The surface is either flush with the surrounding tissues or slightly depressed. Slight but never marked induration appears late in the course of the sore, and it is then seen as a small node about the size of a split pea. A chancre of the entire frenum is usually seen as a linear ulceration (Fig. 11) with a suppurative grayish-yellow floor, the edges of which are raised. Induration, if present, is only slight. Chancres of the frenum are frequently infected, and hence they appear as ulcerations. They therefore simulate nonsyphilitic sores.

INTRA-URETHRAL CHANCRE

In the majority of all cases of intra-urethral chancres a varying amount of the sore can be seen as a portion of it spreads over the edge of the meatus. This portion is a dull red, sharply circumscribed erosion, which, when infected, has a dirty gray surface. Induration is always present and can be easily felt by pressing the glans from above downward between the forefinger and thumb. When the chancre is wholly intra-urethral, the only objective evidence is induration. Slightly painful urination and a blood-tinged, serous discharge are accompanying symptoms of these chancres which not uncommonly lead to a wrong diagnosis of gonorrhea.

MIXED INFECTIONS (CHANCROID AND CHANCRE)

Simultaneously with the inoculation of syphilis, infection with a chancroid or pyogenic organism may occur. During the incubation period of the chancre, the accompanying nonsyphilitic sore remains unchanged. At the end of this period the clinical characteristics of the chancre appear. Induration raises the floor of the sore, and hence the raised and undermined edge disappears as the surface becomes flush with the surrounding parts. The dark-field examination may be positive. The Wassermann reaction is not positive at this time, but becomes so later. It is by reason of the possibility of mixed infection that every genital sore should be considered syphilitic until proved otherwise. Erosive and gangrenous balanitis is another infection which may occur simultaneously with a chancre. This infection is supposed to be caused by a symbiosis of a vibrio with *Spirochaeta balanitidis.* The lesion is seen in two forms, mild and severe. In the mild form, balanitis erosiva circinata, the lesion appears as whitish patches involving the sulcus, the roll of the prepuce or the glans. Phimosis rapidly develops as an essential factor, since these organisms are anaerobic. In the severe form the parts involved become ulcerative and gangrenous with subsequent sloughing. In the mucopurulent discharge from beneath the foreskin, the alleged causative agent, *Spirochaeta balanitidis,* can readily be demonstrated, although *Spirochaeta pallida* is also seen if a mixed infection is present. The two organisms are easily differentiated, as *Spirochaeta balanitidis* is coarser and moves with considerably more rapidity than *Spirochaeta pallida.* In stained preparations both the vibrio and the spirochete are seen.

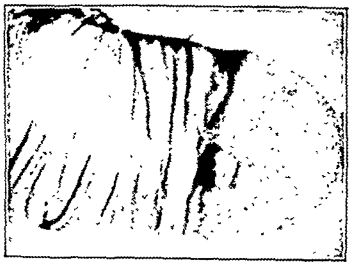

Fig. 9.—Abrasive orbicular chancre, glans: duration, three days; no previous local treatment; dark field +++; Wassermann reaction —. This sore was the size of a split pea, circular in outline; the floor was uninfected and red; the edges were a little below the level of the surrounding parts.

PHIMOSIS AS A COMPLICATION OF CHANCRE

This complication most commonly develops subsequent to chancres in the roll of the prepuce and in the sulcus. In the 121 chancres, phimosis was present in sixteen, or 13.2 per cent., whereas, in seventy-five cases of chancres occurring in sulcus and prepuce in this series, it was present in 61.3 per cent. As already mentioned, uncleanliness, the absence of air, and the presence of moisture predispose to a pyogenic infection and balanitis, which subsequently leads to a phimosis. An additional and sometimes the only etiologic factor is the widespread indurative infiltration of the lymphatics. A diagnosis in the presence of this complication may be made by inspection and palpation alone. The characteristic syphilitic edema of the entire foreskin is present, and in addition it is more swollen on the side on which the sore is present (Fig. 12). A localized indurative mass, or the "collar" form of induration, is palpable beneath the foreskin. A mucopurulent discharge is almost always present, and on this account the diagnosis of gonorrhea is frequently made. Syphilis is not suspected until the appearance of the secondary eruption. It is therefore important in cases of phimosis, venereal in origin, that the presence of a chancre beneath the foreskin be excluded. Occasionally in some of these cases the foreskin may be sufficiently retracted to expose partly the genital lesion for a dark-field examination. If this is not possible, the secretion from beneath the foreskin should be examined for the presence of spirochetes. If this examination is negative, the serum obtained from puncturing the inguinal lymph nodes should be examined.

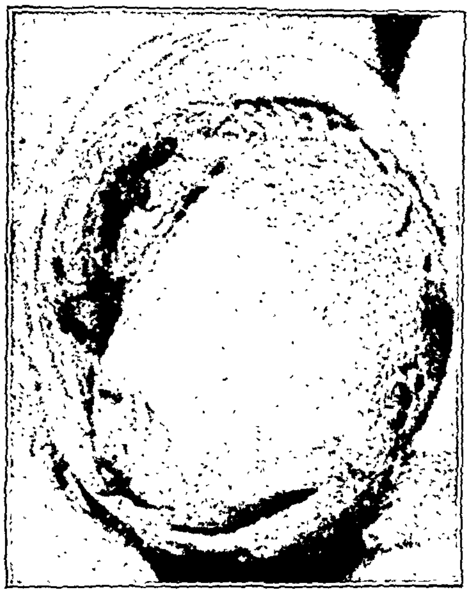

Fig. 10.—*Ulcerative, indurative chancre, sulcus: duration, one month; treated locally with silver nitrate; dark field +; Wassermann reaction ++++. Note the extensive area of infection and ulceration; the floor was covered with a foul-smelling, yellowish-green secretion; induration was present beneath the entire area; in addition, there was a raised and crescentic form of induration involving the right side of the prepuce just beyond the sulcus.*

COMMENT

In the proper treatment of any infectious disease with a specific drug or serum, the earlier the treatment is administered the greater is the prospect of cure. This is undoubtedly true in the treatment of one type of pneumonia with its specific serum, in malaria with the use of quinin, and in other diseases in which specific therapeusis is indicated. The proper treatment of syphilis is no exception to this fundamental principle. On this vital principle may depend the fate of the syphilitic. If this opportunity is lost his fate may "hang upon a thread," depending on the localization of the spirochetes in his body. It has been appropriately said that the syphilitic lives with the sword of Damocles suspended above his head. The necessity of early diagnosis and treatment should be deeply and indelibly engraved on the mind of every physician who has to deal with genital lesions. It is incumbent on the physician to remember that a short interval may exist between an apparently innocent genital lesion and a latent state of paresis. Every syphilitic in the early stage of his infection is a potential tabetic or paretic.

The obsolete separation of syphilis into three stages is possibly unjustified from a pathologic view. Our modern conception of the disease justifies the belief that there is no demarcation between the stages of the disease, and that infection becomes generalized within a few hours after inoculation, becoming more and more intense until the secondary eruption appears.

In the light of our modern knowledge of syphilis and the means at our disposal for early diagnosis and the valuable therapeutic agents at hand for treatment, it seems inconsistent and criminal that secondary eruptions of syphilis are so frequently seen. Yet, in this series of genital chancres the average duration of the chancre was 34.4 days, and a secondary eruption was present in 24.7 per cent. The time is at hand when a secondary eruption of syphilis should be a dermatologic rarity, and the occasion of such a diagnosis should imply carelessness on the part of the physician first seeing the patient for his failure to diagnose the chancre. The only excuse is to be found in the fact that patients with secondary syphilis commonly give the history of having had very recently a "chancroid" which was "burnt" with a silver nitrate stick before an opportunity was given to the physician for correct diagnosis. The question may therefore be appropriately asked, "Who first sees and treats the majority of patients with primary syphilis?" The answer usually is, "quacks," the corner druggist, and the physician who as a routine treats all genital lesions with silver nitrate, and who either entirely neglects the valuable means at hand to diagnose the syphilitic lesion, or is ignorant of these methods.

Local treatment of a chancre with a spirocheticidal drug interferes temporarily or permanently with finding the spirochetes by dark-field examination; hence such treatment prevents the early diagnosis of a chancre and consequently the institution of treatment. The common practice of treating genital sores locally with silver nitrate or other equally powerful spirocheticidal drug before they are properly diagnosed should be discouraged. A routine dark-field examination of every genital sore as a means to an early diagnosis should be the rule rather than the exception.

We cannot hope to make any considerable progress in the prevention of syphilis and the consequences of syphilis until two movements are carried out: first, the education of the public regarding the infection so that the individual with a genital lesion will go to a reputable physician, and second, the education of the medical profession concerning the available means to an early diagnosis of syphilis. As long as the use of the dark-field apparatus and the spinal puncture needle are ignored, just so long will syphilis and its manifold manifestations remain a scourge to humanity.

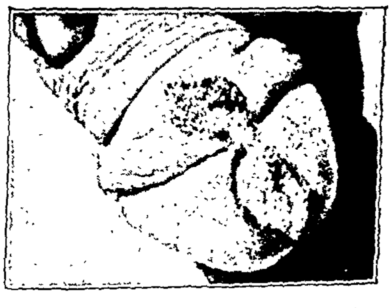

Fig. 11.—Ulcerative chancre of the frenum: duration, from fifteen to twenty days; previously treated with silver nitrate; dark field +++; Wassermann reaction +. The part of the sore involving the foreskin was clinically a chancre; the part involving the glans, however, presented the picture of a nonsyphilitic sore, except that its surface was freely secretive; induration was absent; note the edematous foreskin.

SUMMARY

To prevent the spread of syphilis and to insure a cure, it is imperative that the diagnosis be made at the earliest possible moment.

The average duration of the genital chancre in this series of 115 cases was 34.4 days. A secondary eruption of syphilis was present in 24.7 per cent. Local treatment had been applied to the chancre in 66 per cent.

The means at our disposal for the early diagnosis of syphilis are the dark-field apparatus, the Wassermann reaction, and clinical evidence.

A positive dark-field examination was obtained in 57.1 per cent. of this series. The shorter the period from the appearance of the chancre, the more likely it is that the dark-field examination will be positive. The converse is true with the Wassermann reaction. Therefore, the dark-field apparatus is not only the preferable laboratory test, but it is also more successful than the Wassermann reaction in the diagnosis of early syphilis.

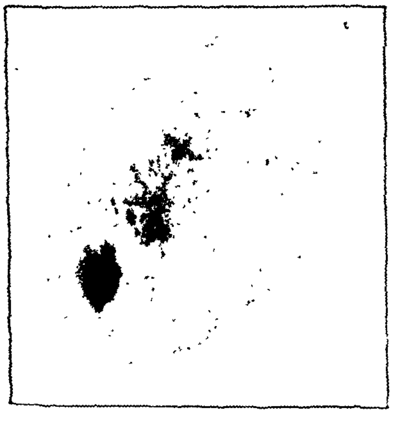

Fig. 12.—Concealed chancre, sulcus, phimosis: duration, from ten to fourteen days; treated locally; *dark field not possible*; Wassermann reaction —. The foreskin was edematous, markedly inflamed and adherent; there was a mucopurulent discharge, shown as a white streak in the illustration; a hard mass was palpable in *the right sulcus*, and visible as a raised portion (left side of illustration); on account of the urgency of the condition, arsphenamin was promptly given; after the acute condition subsided, the foreskin was retracted, and the indurated remains of a chancre were seen in the floor of the right sulcus.

The too common practice of treating genital chancres with a spirocheticidal drug before they are properly diagnosed may prevent or greatly delay the obtaining of a positive dark-field examination.

A positive Wassermann reaction was obtained in 74.1 per cent. of this series. This reaction in late primary syphilis is the most successful laboratory method for diagnosis.

Both laboratory tests were negative in 8.6 per cent. Therefore, by the use of both tests, 91.4 per cent. of the chancres in this series were diagnosed by laboratory methods alone. However, by the use of these tests alone, delay may be experienced before the spirochetes are found in the secretion from the chancre, or before the Wassermann reaction, if negative, becomes positive, or before the report of this test is obtained. Treatment is therefore delayed, and delay at this time may be fatal and may mean an involvement of the nervous system. Moreover, if a chancre is seen in the negative stage of a Wassermann reaction, and if the dark-field examination is negative, it is not ideal to await the appearance of a positive Wassermann reaction for diagnosis.

A definite clinical diagnosis of a genital chancre can often be made. If a genital sore is clinically a chancre, and if the dark-field examination and the Wassermann reaction are both negative, it is perhaps better to start intensive treatment rather than await the appearance of a positive Wassermann reaction.

Criminal Tendencies of the Defective.—We are able to predict that with the exception of the lightest grade cases of dementia praecox and the higher grades of the feebleminded, who make up the occasional criminal, hypermorons, that the others are all marked for slaughter; that they cannot adjust themselves to a normal environment.—Hickson.

A GROUP OF INTERESTING SYNDROMES RESULTING FROM MULTIPLE EMBOLI

OBSERVATIONS IN A CASE OF CHRONIC BACTERIAL ENDOCARDITIS

C. SAUL DANZER, M.D.
Attending Physician, University and Bellevue Hospital Medical College Clinic and Sea View Hospital
BROOKLYN

The case that forms the basis of this paper is of importance, first, because of the polymorphism of symptomatology of a relatively common disease, endocarditis, and secondly, because the old clinical aphorism whereby one attempts to group most, if not all, of the symptoms of a given case under a common heading, is reemphasized.

REPORT OF CASE

History.—A white man, aged 42, whose family history was significant only in that his mother died of heart disease, had smallpox twenty-six years before he came to my attention. Six years after having smallpox he suffered from an undetermined disease, which, so far as he can remember, consisted of fever and cough. He apparently recovered from this and was well up to one year before I saw him, when he had an attack of what he terms the grip, which began with severe dyspnea (almost to the point of suffocation), necessitating the summoning of an ambulance and the administration of a hypodermic injection to relieve him. He then coughed and had fever, and the next night hemoptysis.

After three weeks there was an acute inflammatory condition of the right foot. Then there came a sudden pain in the right elbow, followed by an appreciable smallness of the pulse on that side. To put it in the patient's own words, "he felt that the throbbing of the arteries, which was present in both arms, had suddenly stopped on the right side."

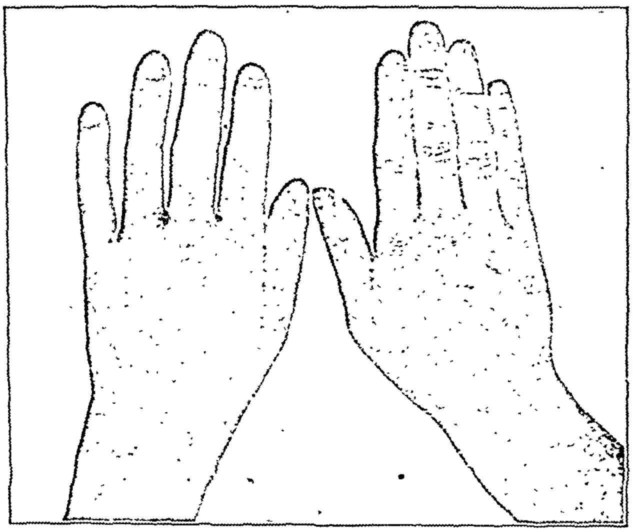

Fig. 1.—Edema and swelling of left hand.

Later he had a sudden attack of severe pain in the left knee that radiated up the thigh and down the leg, but there was no accompanying inflammatory condition of the knee joint proper. This condition gradually improved and he was fairly comfortable for a few months. But his well-being was not to be lasting, for he suddenly lost power in the left arm and left leg, and the angle of the mouth drooped on the *right side*. The latter fact was elicited by having the patient imitate the condition of facial contortion that existed at the time. Consciousness, however, was retained throughout the hemiplegic attack. In a few days he recovered power in his leg, but the arm was still weak. Two months later he noticed swelling of the hand and fingers of the paralyzed arm which, after disappearing and recurring a few times, finally remained. Up to the present time no other change had occurred. There was also pain in the shoulder and elbow of the paralyzed arm that dated back to the hemiplegic attack. The sharp pains that occurred in the shoulder and elbow joints of the paralyzed arm, I regard as being due to the arthritis that often accompanies a hemiplegic extremity and are therefore of different origin from some of the other painful conditions of the extremities that accompanied this case.

Examination.—The patient was poorly nourished, was dyspneic, and the lips, nose and ears showed cyanosis. He held his left arm slightly flexed at the elbow, guarding it carefully, as if to ward off possible harm. Handling the arm in any but a gentle manner made the patient wince with pain, localized principally in the shoulder joint.

His face showed the presence of old smallpox depressions. The gums and teeth were in poor condition, and the tonsils were ragged. In the neck the carotid pulsations were marked.

The lungs were negative except for a few moist râles, generally distributed over both lungs.

The apex beat of the heart was heaving, of the so-called choc-en-dome variety, and was situated in the fifth and sixth interspaces about three-quarters inch outside the midclavicular line. At the aortic orifice a systolic murmur was very prominent and was transmitted to the vessels of the neck, and at Erb's point (third interspace to the left of the sternum) a soft diastolic murmur was also heard. At the apex there was a loud systolic murmur, transmitted to the axilla and the back and preceded by a presystolic rumble.

At a later date, and after digitalis therapy had been employed, the diastolic murmur at the aortic orifice disappeared, proving the latter to be relative and due to the widening of the aortic ring, because of the loss of myocardial tone. The presystolic murmur at the apex also disappeared.

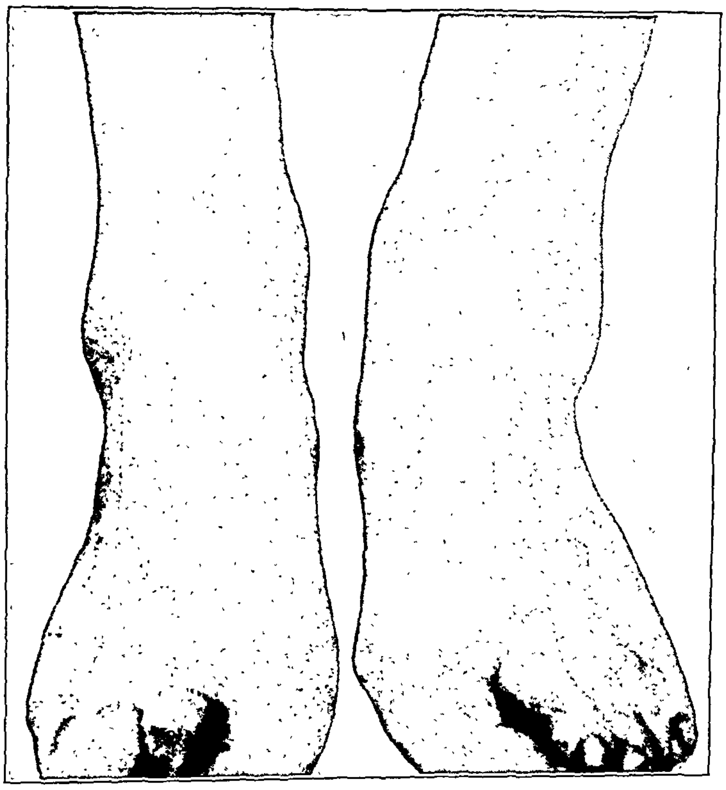

Fig. 2.—Periarticular swelling around left ankle.

The blood pressure on the right side was: systolic, 123; diastolic, 46; on the left side: systolic, 135; diastolic, 43.

The left border of the heart was in the axillary line; the right border was about one-half inch to the right of the sternum. The base of the heart was widened, as outlined by percussion. Roentgenoscopy revealed the left border of the heart to be 12 cm. to the left of the midline (the upper limit for normal is 9 cm.); the right border was 5 cm. from the midline (the upper limit for normal is 4.4 cm.). The aorta was widened. Fluoroscopy in all directions, including first and second diagonal positions, ruled out the possibility of an aneurysm.

The abdomen was found to be negative, as were also the tendon reflexes.

The extremities were interesting in the following respects: The left arm was paretic. There was, however, a slight contraction of the biceps, so that the elbow joint was held in a position of flexion. The left hand was markedly edematous, and the fingers were definitely clubbed (Fig. 1). On the left foot there was some periarticular swelling about the ankle, and cutaneous sensibility tests showed the left arm and hand to be hyperalgesic as well as hyperesthetic. The deltoid and the biceps muscles of the left arm were atrophied because of disuse, resulting from the paralysis and also the painful condition of the shoulder joint.

The muscular reactions of the biceps and the anterior and posterior bellies of the deltoid were as follows: On the left side the faradic response was greater than on the right side: the galvanic anodal contraction, however, was greater than the cathodal on the left side.

The galvanic reactions on the diseased side corresponded, therefore, to those occurring in peripheral nerve disease; but since the faradic response did not indicate such a condition, we may say that the nerve or muscle degeneration present was quite limited in its extent.

The radial pulses were unequal, the one on the right side being much smaller than the one on the left. Arterial tracings confirmed this inequality of pulse beats. They showed, further, that the right radial pulse was of the tardus variety with its gradual rise and fall. Were this the form of the pulse tracings in all the arteries, one would be justified, on that ground alone, almost positively to diagnose a condition of stenosis of the aorta or its orifice. But as this pulsus tardus was confined to the right radial artery, one is justified in diagnosing a stenosis or obstruction to the right radial artery.

The left radial artery gave an anacrotic pulse tracing in which the anacrotic limb, instead of falling, was sustained almost to the time of the dicrotic notch. This was due to the condition of high peripheral resistance, which prevented the rapid emptying of the given segment of the vessel, thus causing the pressure to be sustained, rather than to fall shortly after the rise.

The left brachial artery gave a "bisferiens pulse," with the characteristic notching on the plateau, a condition simply indicating increased peripheral resistance, such as might occur in a sclerotic condition of the blood vessels.

The right brachial tracing showed a smaller pulse than on the opposite side with a more gradual fall of the catacrotic limb.

Roentgenograms of both hands showed a rarefaction of the phalangeal bones near the interphalangeal joints, and also of the carpal and metacarpal bones.

The urinary findings were irrelevant; the blood culture was negative. The Wassermann test was negative and remained so, even after provocative mercurial administration.

COMMENT

A man with chronic valvular disease at the mitral and aortic orifices probably rheumatic in origin, or perhaps gaining entrance through diseased tonsils, was in fairly good condition until last year, when he had an acute attack of what he called the grip and which consisted of severe dyspnea and cyanosis, accompanied by cough, fever and expectoration of blood. This in all probability was a pulmonary infarct, produced by an embolus consisting of a vegetation from a diseased heart valve, or by the breaking off of a thrombus, which perhaps lodged in one of the chambers of the heart.

He then had a sudden pain in the right elbow accompanied by a subjectively perceptible smallness of the pulse on that side, which the radial tracing proved to be a stenosis of the radial artery due to an embolus.

The pains in the right foot and left knee, being unaccompanied by swelling of the joints proper, may be interpreted as embolic, and were probably caused by dorsalis pedis and popliteal artery obstruction, respectively.

The next condition brought to our attention is a hemiplegia affecting the left arm and left leg and the right side of the face. This constitutes the so-called Millard-Gubler syndrome of crossed facial hemiplegia. Since it occurred suddenly and without unconsciousness, we may safely diagnose an embolus as the cause of the syndrome. The seat of disease in this condition is the pons, on the right side, that is, corresponding to the facial paralysis. The artery affected was probably one of the right branches of the basilar artery. We have still to explain the edema of the left hand, the clubbed fingers on that side and the rarefaction of the bones of the left hand producing a picture of osteoporosis. I think that these may be grouped under the heading of trophic disturbances, due to a hemiplegia, and those due to pontile lesions, according to Purves Stuart,[1] are not infrequently accompanied by severe vasomotor disturbances. Parenthetically, I would say that the trophic changes in bone may be even severe enough to cause spontaneous fractures in cases of hemiplegia.

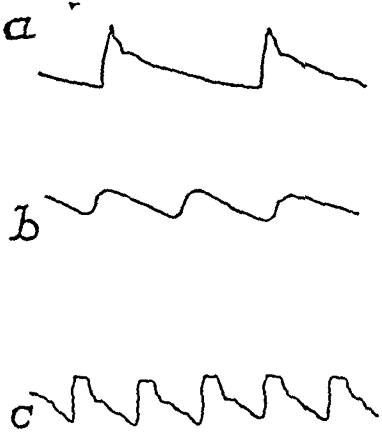

Fig. 3.—Pulse tracings: *a*, normal; *b*, right radial, pulsus tardus; *c*, left radial, anacrotic pulse.

Although the blood culture was negative, we regard this case as one of bacterial endocarditis in the bacteria-free stage. The organism is most likely of the *Streptococcus viridans* type. This brings our case in the class described by Schottmüller[2] as "endocarditis lenta" and by Libman[3] as "subacute infective endocarditis."

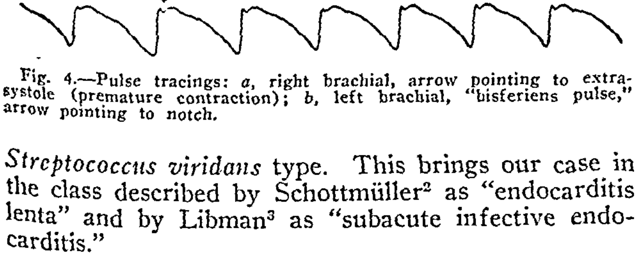

Fig. 4.—Pulse tracings: *a*, right brachial, arrow pointing to extrasystole (premature contraction); *b*, left brachial, "bisferiens pulse," arrow pointing to notch.

Keeping Fit.—You can't go far if you don't keep fit.—*Bulletin*, Kansas State Board of Health.

HOOKWORM INFECTION AMONG TROOPS

TREATMENT WITH OIL OF CHENOPODIUM *

R. H. KNOWLTON, M.D. (St. Petersburg, Fla.)
First Lieutenant, M. C., U. S. Army
CAMP JACKSON, COLUMBIA, S. C.

Darling, Barber and Hacker[1] recently gave the results of their extensive study of the treatment of hookworm infection carried on in the Far East. The present investigation was largely patterned after their methods, but with two main objects in view: first, to get some idea of the severity of hookworm infection among Southern troops, and second, to check up the efficiency of the treatment used in this hospital. With the exception of thirteen negroes in Table 1, who came from their organizations, all the subjects used were chosen at random from the convalescents in the wards without reference to the degree of infection, although all were known to have positive stools. They were practically all from the Carolinas and Florida. A few had received treatment at their homes, but it does not seem to have been very effective, as one patient with 1,263 worms had received one treatment two months previously, one with 559 worms had received five, and one with 313 worms had received six.

The work was first undertaken in the hospital wards, but there was so much chance for error and the data were so incomplete that these results have largely been discarded, and none of them included in Tables 1, 2 and 3. A special building was then set aside for the work in which the patients lived and where all work was carried out. The object and methods of the investigation were explained to the patients, and they assisted greatly in the work. They were cautioned to avoid all fruits and fibrous vegetables while under treatment. Each patient had his own commode under his bed, with his name on it, and the stools were examined for forty-eight hours. The method of washing stools and removing worms was essentially that described by Darling, Barber and Hacker. The contents of a container were rinsed into a copper sieve (50 mesh) and then washed by a jet of water from a rubber tube attached to the tap. The residue containing the worms was rinsed into flat glass dishes and examined against suitable black and white backgrounds. Some of the patients became quite expert in picking out the worms, and there was a friendly rivalry as to who should have the most.

METHODS OF TREATMENT

According to the routine treatment used at this hospital, a light supper is ordered the night before and a full dose of magnesium sulphate is given about 8 p. m. No breakfast is taken in the morning, and 1.8 c.c. of oil of chenopodium is given in six gelatin capsules (supplied by a pharmaceutical house), two every hour for three doses. Two hours after the last capsules, another full dose of magnesium sulphate is given. This method was followed in the first series and the results are tabulated in Table 1. Table 2 shows a similar group of cases which were treated in the same way with the same oil expressed from the proprietary capsules. The oil was collected in a graduate and measured in a pipet, and exactly 0.3 c.c. put into hard gelatin capsules, which are very soluble in water. In every case, whatever the laboratory findings may have been, each patient received at the end of four days a second treatment with freshly expressed oil, and this was repeated at similar intervals until it was evident that all worms had been removed.

---

EFFICIENCY OF SOFT CAPSULES

In determining the efficiency of any method of treatment, the number of cures alone does not give a fair estimate, since the drug used may leave 2 or 3 per cent. of the worms and still be highly efficient, but the case does not count as a cure. By figuring the total percentage of worms removed from a group of patients, we obtained a much better index, but this has one objection—that one or two large carriers may dominate the result, while the man with a very few worms hardly influences it at all. If the percentages destroyed by one treatment in each individual of a group of patients are averaged, we again get a fairly good index; but here the man with one worm counts the same as the one with a thousand. Therefore it was decided to use both of the latter methods and average the results, obtaining a value which is spoken of as the efficiency index. The balance is similar to that of our Congress, on one side the representation based on population, and on the other, each state counting equally.

Average					78.18

Average of percentages	78.18
Percentage of grand total of worms removed by one treatment	58.86
Average or efficiency index	68.5

Table 1 gives the results obtained from the group treated in the routine manner with soft gelatin capsules. In this table it is seen that the first thirteen patients are negroes, and the results obtained were quite satisfactory. It is difficult to say whether this is due to their superior power of digestion or to the fact that the capsules used were a new lot and very fresh; at any rate, the later results among the white patients were far less satisfactory.

TABLE 2.—RESULTS OF ONE TREATMENT WITH OIL OF CHENOPODIUM

Total			4,601	4,402	3,082.1
Average					93.40

Average of percentages	93.40
Percentage of grand total of worms removed by one treatment	95.67
Average or efficiency index	94.5

It will be seen that the efficiency of the soft capsules is fixed at 68.5 and that of the fresh oil at 94.5. The question now arises as to what this marked difference is due—whether to a lack of dosage in the soft capsule or to its lack of solubility. The chemistry department of the laboratory undertook to ascertain the contents by this method: Twenty-five capsules were placed in a graduate in water and the volume read off. They were then removed, dried quickly by blotting, and cut open. The empty shells were then put in water and the volume again taken. The difference represents the amount of oil in twenty-five capsules. By this method the contents were found to be about 73 per cent. of that stated, but there may be errors in this calculation, as, for instance, absorption of the oil into the gelatin.

Darling, Barber and Hacker, in their report, give a number of figures bearing on this point. Using as efficiency index the group percentage of worms removed by one treatment, they found that the result of divided doses of oil of chenopodium was: 2 c.c., 95.18 per cent.; 1.5 c.c., 88.7 per cent.; 0.75 c.c., 80 per cent., and 30 minim soft gelatin capsules, 66.4 per cent. This shows distinctly that the insolubility is the main factor, as even 0.75 c.c. of the fresh oil was superior to the soft gelatin supposed to contain 2 c.c. It is interesting to note the similarity of these figures to those shown in the foregoing tables, with particular reference to the low efficiency of the soft gelatin capsules. Those used by Darling, Barber and Hacker were old. Those used here were obtained fresh, but from another manufacturer.

INSOLUBILITY OF CAPSULES AS CAUSE OF POOR RESULTS

Based on the idea that the insolubility was the main factor, a small group of patients was treated with three soft and three hard capsules. If the cause of the poor results of the routine treatment was the lack of dosage, the index would presumably be midway between that of Table 1 and Table 2. On the other hand, if the insolubility was the main factor, it was thought that perhaps the best results of all might be obtained. That is, the very soluble capsules would dissolve in the stomach and the oil be effectual on those worms high up in the intestinal tract, while the tougher, soft capsules would break up later on, and not losing any effectiveness by absorption, would care for the worms lower down. Table 3 shows this group of cases.

TABLE 3.—RESULTS OF ONE TREATMENT WITH OIL OF CHENOPODIUM

1.8 c.c.: 0.9 c.c. in Soft Capsules, 0.9 c.c. in Hard (Soluble) Capsules

Case Number	Hemoglobin	Total No. of Worms Found	No. Removed by First Treatment	Percentage Removed by One Treatment
1	..	52	50	96.2
2	65	919	892	97.1
3	75	130	130	100.0
4	80	81	76	93.8
5	75	40	40	100.0
6	85	10	9	90.0
7	75	364	361	99.2
8	80	47	45	100 0
9	85	26	25	96.2
10	80	169	153	90.5
Total..........		1,836	1,781	963.0
Average..........				96.3

Average of percentages..........	96.3
Percentage of grand total of worms removed by one treatment...	97.0
Average or efficiency index..........	96.7

These results indicate that the factor is not insufficient dosage, and apparently is the lack of solubility. It should be stated, however, that this series of cases was an afterthought, and in the second treatments in some of the cases the stools could be examined for only twenty-four hours. In previous cases, however, experience has shown that the early stools are the important ones, those of the second day showing little or nothing. The efficiency index of this group is determined at 96.7, slightly better even than the hard capsules alone (94.5), and very markedly superior to the soft capsules at 68.5.

OTHER OBSERVATIONS

In most of these cases the hemoglobin was taken by a Tallqvist scale in order to ascertain whether it gave any indication of the amount of harm the infection was doing to the patients. Table 4 shows the result in eight groups of patients classified according to the number of worms. It is not practical to figure very closely on a factor which is as uncertain as the hemoglobin estimation, but as it stands, it appears there is no particular reduction in anything under 500 worms. In all other degrees of infection, most patients were found in the 80-89 group.

TABLE 4.—CORRELATION BETWEEN HEMOGLOBIN AND NUMBER OF WORMS

Number of Worms	Hemoglobin			
	60 to 69	70 to 79	80 to 89	90 to 100
1 to 25	0	4	9	2
26 to 50	0	4	4	0
51 to 100	0	1	5	3
101 to 200	0	4	8	0
201 to 350	0	1	5	1
351 to 500	0	1	2	0
501 to 1,000	1	0	1	0
Over 1,000	2	1	0	0

Table 5 shows the incidence of worms in the two races. Although the number of negroes is rather small, it seems evident that they are less heavily infected than *white persons.*

TABLE 5.—INCIDENCE OF WORMS BY GROUPS

Number of Worms	Number of White Cases	Number of Colored Cases
1 to 25..........	19	11
26 to 50..........	10	4
51 to 100..........	11	1
101 to 200..........	14	2
201 to 350..........	7	0
351 to 500..........	3	0
501 to 1,000..........	2	0
Over 1,000..........	3	0
Total..........	69	18

The average number of worms in sixty-nine white patients not previously treated in this hospital was 155.3. In eighteen negroes the average was 38.3. Three white patients had 1,010, 1,263 and 1,704 worms, respectively. The last patient was a thin, pale boy very evidently weakened by his disease, and before he was discharged his appearance and weight had improved remarkably.

In all cases except a few of the heaviest infection, the number of worms of each sex was determined to see which was the more resistant to the oil. Table 6 shows that there is no difference at all and that the larger female has no more resistance than the smaller male.

During this work, the patients were under close observation following the treatment, and it was possible to observe any symptoms of poisoning if they were present. In taking the fresh oil, the patients usually felt like lying down after the second or third dose, and, as a rule, they remained quiet during the day; but they were always ready to eat when they were allowed to, and felt better afterward. There was no vomiting except occasionally after the purge, and there were no other toxic symptoms except a feeling of weakness, of which all complained. This passed off in a few hours, and in the morning they were about as usual. The patients of the first series agreed that the hard capsules made them sicker than the soft, but there were no objective signs of toxic action of the drug.

TABLE 6.—INCIDENCE OF WORMS BY SEX

	Number	Per Cent.
Removed by first treatment:		
Females..........	3,702	56.5
Males..........	2,854	43.5
Total..........	6,556	
Removed by later treatments: i. e., survivors of first treatment:		
Females..........	380	56.0
Males..........	299	44.0
Total..........	679	

CONCLUSION

The results show that while in a considerable proportion of soldiers the infection is light, all grades are encountered and a few may be termed as severe. The negro appears to be less *severely infected than the* white race. The soft gelatin capsules stated to contain 5 minims are distinctly less efficient than a similar dose placed in soluble capsules.

VACCINATION OF TUBERCULOUS PATIENTS AGAINST SMALLPOX

RESULTS IN TWO HUNDRED CASES

LOUIS MARK, M.D.
MOUNT VERNON, OHIO

A review of the small amount of literature on the subject of vaccination against smallpox of tuberculous patients and personal consultation with several men of authority reveal the fact that it is apparently a natter of common agreement that vaccination should t be done unless it is extremely necessary for the afety and welfare of the patient.

The results obtained in compulsory vaccination of about 200 patients with pulmonary tuberculosis seem strongly to contradict this idea.

The reason for the compulsory vaccination was that a virulent case of smallpox broke out in the institution and the patient had been mingling with all the other patients for about ten days prior to the time of the eruption and the making of the diagnosis.

REPORT OF CASE

W. Mc., man, aged 34, white, admitted, Aug. 2, 1918, with the ordinary history of a tuberculous breakdown, was well nourished and was only 5 pounds underweight, weighing 170 pounds. He had no cough and very little expectoration, but what there was gave a positive reaction for tubercle bacilli. Chest examination revealed very little. The patient was classed as incipient (Turban Stage I).

August 12—ten days after admission—the patient's temperature rose to 102.6. He complained of headache, general malaise, nausea, vomiting and constipation. Chest examination disclosed no cause for the rise of temperature. On the 16th his temperature dropped to subnormal and he developed an eruption. A diagnosis of smallpox was made, which was confirmed by the state dermatologist.

VACCINATION OF THE OTHER PATIENTS

As the patient had been mingling with the other patients and employees in the main dining hall and cottages, compulsory vaccination was decided on, and all patients, regardless of stage or activity, were vaccinated, August 17. The number vaccinated was 200, made up of seventy in the first stage, eighty-three in the second, and forty-seven in the third. The majority had some activity and some elevation of temperature. Among these patients there were forty who either had never been vaccinated before, or had been vaccinated with negative results.

Three weeks after vaccination all cases were closely observed, and it was found that there were about 50 per cent. positive vaccinations. Fifteen per cent. of the patients had sore arms and 8 per cent. were "on tray" for one or more meals. On the ninth day after vaccination, one patient developed a typical varioloid eruption about the neck and also had a positive vaccination on the arm. Several patients who had to be kept on tray had a rise in temperature which lasted for a day or two and was present at the time the redness, swelling and soreness of the arm were the greatest. There were no instances in which patients complained of any conditions pertaining to the chest that could in any way be traced to the vaccination. The majority of the patients were examined three or four weeks after the vaccination, and in no case were there any changes incompatible with the usual course of tuberculosis.

In reviewing the results obtained from this series of vaccinations, it would appear that when a case of smallpox breaks out among tuberculous patients and there is a possibility of a spread of the disease among the patients, compulsory vaccination is advisable.

The results obtained in far advanced cases could not be differentiated from the results obtained in the first and second stage cases, and it would seem, therefore, that these cases should not be exempted when considering vaccination. Although it would not be advisable to vaccinate all patients against smallpox when first admitted to an institution, yet it should be done at once when the necessity arises.

The smallpox patient made a normal recovery from his smallpox and was discharged from the institution within three months as an apparently arrested case of pulmonary tuberculosis. His sputum was negative for tubercle bacilli on discharge. No other cases of smallpox developed at the institution.

STREPTOCOCCUS PNEUMONIA

JAMES G. CUMMING, M.D. (Ann Arbor, Mich.)
Lieutenant-Colonel, M. C., U. S. Army

CHARLES B. SPRUIT, M.D. (Boston)
Captain, M. C., U. S. Army

ERNEST J. ATEN, M.D. (Coraopolis, Pa.)
First Lieutenant, M. C., U. S. Army

NEWPORT NEWS, VA.

At Fort Sam Houston, Texas, during the winter of 1917-1918, it was noted that the majority of pneumonia cases presented a clinical type not often seen in civil practice. The patients were highly septic; the pneumonia, for the most part, followed measles, and when not fatal, it often terminated in empyema. It was further observed that the usual type of lobar pneumonia was often complicated by relapses, which were attributed to delayed resolution. The frequency of what we shall call, for the present, septic pneumonia, and its occurrence as a complication of measles, led to an investigation as to the causative organism in this type of the disease, as well as in the complicated, so-called lobar pneumonia. It is well known that the hemolytic streptococcus is almost exclusively the causative organism of complications in scarlet fever cases; and since pneumonia is not an uncommon complication of this disease, we were led to map out a bacteriologic investigation of measles and pneumonia cases; this included the identification of this organism.

As previously reported, it was readily determined that a large percentage of measles patients harbored the hemolytic streptococcus in their throats on entering the hospital, and further, that this organism was found in practically all specimens of sputum from septic pneumonia patients, also in the pus from empema patients, and finally in the blood stream shortly before death.[1] Furthermore, this organism was found in the throat, sputum, empyema pus, and blood stream of many patients suffering from so-called lobar pneumonia.

It would seem that this organism is of sufficient importance to warrant a brief consideration of its epidemiology. Epidemiologic studies of the occurrence of more or less extensive milk-borne epidemics of tonsillitis or septic sore throat in England, as well as in this country, chiefly in the vicinity of Boston, Chicago and Baltimore, make plain the epidemiology of hemolytic streptococcus infection. It is the opinion of Smith and Brown that the organism is of human origin, that it gains access to the cow's udder from infected milkers, and that milk is the chief, if not the only, disseminator of this disease on a large scale, in these milk-borne epidemics. Smillie reports its frequent occurrence in the throats of scarlet fever patients and in the blood stream in the fatal cases. It has been isolated from the blood stream of septicemia patients following trivial wounds, and is now believed to have been the chief cause of sepsis following childbirth.

---

[1] Cumming, J. G.; Spruit, C. B., and Lynch, Charles: The Pneumonias: Streptococcus and Pneumococcus Groups, J. A. M. A. 70: 1065 (April 13) 1918.

In pursuance of our plan of investigation of throat swab cultures from measles patients, it was at first believed that we should determine the prevalence of type pneumococci as well as hemolytic streptococci. But owing to the early discovery that the hemolytic streptococcus was the predominant, if not the sole, cause of pneumonia following measles, we later limited our investigation to the identification of hemolytic streptococci.

HEMOLYTIC STREPTOCOCCUS CARRIERS

With the view of determining the percentage of hemolytic streptococcus carriers among measles patients on entrance to the hospital, throat swab cultures were taken in 452 cases. These fell into two groups, one showing Types I and II,[2] and the second showing Type III.[3] Of these, 294, or 64 per cent., showed Types I and II hemolysis, while 158, or 35 per cent., showed Type III hemolysis. Among the 294 patients showing Types I and II hemolytic organisms, thirty, or 10 per cent., developed these complications: otitis media, four; bronchopneumonia, five; tonsillitis, seven; scarlet fever, three; lobar pneumonia, two; acute bronchitis, seven; erysipelas, one; cellulitis, one.

In contrast to the foregoing group, which shows 10 per cent. of complications, we find that among 158 patients showing Type III hemolytic streptococci, sixty-five, or 41 per cent, developed complications. These were: bronchopneumonia, fifty-two; empyema, nineteen; tonsillitis, nine; otitis media, eight; arthritis, four; acute bronchitis, five; mumps, one; lobar pneumonia, one; cellulitis, six. These eighty-four complications occurred among the sixty-five patients harboring streptococci.

If only the pneumonia cases are considered in these two groups of findings, it will be noted that among those measles patients from whom organisms showing Types I and II hemolysis were isolated, only 2 per cent. developed pneumonia; while among those harboring Type III hemolytic streptococcus, 32 per cent. developed pneumonia. The incidence in percentages was sixteen times greater among streptococcus carriers.

Considering the total pneumonia cases in both groups of throat findings among measles patients, it is shown that of the 452 cases, 12 per cent. developed pneumonia, and over 94 per cent. of this 12 per cent. occurred among streptococcus carriers.

In this series of cases it has been established that 35 per cent. of the measles patients were hemolytic streptococcus carriers on entering the hospital, and that 33 per cent. of these developed streptococcus pneumonia; while among the 65 per cent. of patients who were noncarriers, only 6 per cent. developed this complication.

In contrast to the high percentage of hemolytic streptococcus carriers among measles patients, it is pointed out that among 168 swabs from average throats, there was found only 6 per cent. streptococcus carriers. This percentage corresponds to that obtained by Smillie in his investigation of hemolytic streptococci in Boston. It is a significant fact that there are six times more streptococcus carriers among measles patients than among average well persons.

It might seem that the streptococcus in the throat of a carrier prepares the way for measles virus infections, and that the latter infection, in turn, produces a condition—lowered resistance—that favors streptococcus pneumonia—an extension of this infection to the lung, the pleural and pericardial cavities, and the blood streams, joints, etc.; or it is possible that both infections occur simultaneously through the same avenue of transmission. In order to determine whether or not measles patients are streptococcus carriers prior to measles infection, it is suggested that at least 1,000 recruits at some camp be examined for this organism, dividing these into carriers and noncarriers, and that they be kept under observation for the occurrence of measles in the two groups. Are streptococcus carriers more susceptible to virus infections?

BACTERIOLOGIC FINDINGS IN ANTEMORTEM PLEURAL EXUDATES AND BLOOD OF PATIENTS WITH PNEUMONIA FOLLOWING MEASLES

Of ninety-two examinations of pleural exudates from patients in the pneumonia wards, organisms were found in seventy-four specimens. Of forty-six specimens from patients diagnosed as having lobar pneumonia, 61 per cent. proved to be pure hemolytic streptococcus, and 39 per cent pneumococcus. Of twenty-eight bronchopneumonia specimens, 86 per cent. were streptococci and 14 per cent. pneumococci. By consolidating these two groups we find that 72 per cent. were hemolytic streptococci and 28 per cent. pneumococci. From these figures it would appear that clinically there is either a considerable error in the differential diagnosis of the pneumonias, or that a large percentage of the lobar types are complicated by streptococcus infection.

From patients with pneumonia following measles, thirty-eight blood specimens were examined. Of these, twenty-nine were negative, while nine, or 24 per cent., were positive for hemolytic streptococci. With few exceptions these positive specimens were obtained within twenty-four hours before death, showing that the blood stream invasion with this causative organism was a late event. In the series of necropsies to be reported, 52 per cent. of heart's blood cultures were positive.

BACTERIOLOGIC FINDINGS AT NECROPSY

In thirty-four necropsies on nine lobar pneumonia and twenty-five bronchopneumonia patients, streptococci—Type III hemolysis—were isolated from twenty-one lung specimens, twenty-three pleural exudates, fourteen pericardial exudates, and sixteen heart's blood specimens.

In twenty-seven, or 80 per cent., of the specimens from serous exudates or heart's blood, the streptococcus was isolated from pure culture, and in four, or 12 per cent., of the specimens it was coexistent with the pneumococcus; furthermore, it was found in one or more of these specimens in thirty, or 88 per cent., of the necropsies, lobar pneumonia cases included.

---

[2] Small area hemolysis representing pneumococcus and Streptococcus viridans.

[3] Large area hemolysis representing Streptococcus hemolyticus colonies.

The streptococcus was isolated from each of the twenty-five necropsies on bronchopneumonia patients. Of these, 75 per cent. were known to have followed measles.

Of the nine lobar pneumonia postmortem specimens rom clinically diagnosed lobar pneumonia cases, in nly four instances was the pneumococcus unaccompanied by the streptococcus. In two others only streptococci were found, and in the remaining three there were both pneumococci and streptococci.

In only one necropsy on a patient that had had pneumonia following measles was a type epidemic pneumococcus found, and this was coexistent with the hemolytic streptococcus; while in the nine lobar pneumonia cases, hemolytic streptococci were found, either in pure culture or coexistent with pneumococci, in five, or 55 per cent., of the necropsies.

It would appear that the hemolytic streptococcus was the immediate cause of death in thirty, or 88 per cent., of the thirty-four cases, lobar pneumonia cases included; and since this organism was found in fairly pure cultures in all lung specimens as well as in pure cultures, in either serous exudates or the heart's blood or both, in cases of pneumonia following measles, it may be concluded that the hemolytic streptococcus is the causative organism in this complication following measles, and moreover, that it was the immediate cause of death in a large percentage of so-called lobar pneumonia cases.

SWAB AND SPUTUM SPECIMENS

Since, in this series of necropsies, the hemolytic streptococcus was identified as the causative organism of bronchopneumonia following measles, a series of sputum specimens was examined in conjunction with throat swabs. Of the swabs, 76 per cent. were positive, as were also 87 per cent. of the sputum specimens. In 55 per cent. of the cases the swabs as well as the sputum specimens were positive; while either swab or sputum was positive in 100 per cent. of the cases. These findings show the importance of taking both swab and sputum specimens.

HEMOLYTIC STREPTOCOCCI IN REMOVED TONSILS

Of 142 removed tonsils, 82 per cent. showed hemolytic streptococci. The tonsil acts as a reservoir for the organism. On removal of the tonsil, the throat rapidly clears of this, the most common of all secondary invading organisms.

IDENTIFICATION AND CLASSIFICATION

On account of the unquestioned prevalence of streptococcus pneumonia, both as a complication of measles and as a coexistent or a terminal infection in lobar pneumonia, it was decided to examine for streptococci sputum specimens submitted to the pneumococcus division for type identification. A total of ninety-two specimens was examined, and forty-nine, or 53 per cent., of these showed Type III hemolytic streptococci. Of these ninety-two sputum specimens, pneumococci Types I, II or III were identified in only 9 per cent. of the cases. Owing to the prevalence of streptococcus infection as a secondary and fatal involvement in lobar pneumonia, as well as in the virus infections, there is need for the instruction of all laboratory workers in the use of the hemolytic plate in the diagnosis of pneumonia. The clinician should insist on a report of the presence or absence of streptococci, as well as of type pneumococci. The importance of these findings in the sputum is substantiated in nine so-called lobar pneumonia cases, in which, at necropsy, hemolytic streptococci were isolated from the heart's blood or serous cavities in 55 per cent. of the specimens.

We are led to believe from our investigations that a diagnosis of Type IV pneumococcus should be made guardedly; furthermore, since massive lobular pneumonia may be incorrectly diagnosed as lobar pneumonia, and as lobar pneumonia involvements may be associated with streptococcus infection, which at Fort Sam Houston gave a mortality of 82 per cent. during January and February, we believe that all specimens of sputum should be examined for hemolytic streptococci as well as for pneumococci. Since the pneumonias are of two main groups—pneumococcus and streptococcus—and as these may be coexistent, the isolation of the causative organism or organisms in pure culture is essential to group as well as to type identification.

The value of routine streptococcus identification will become of particular importance in the event of the successful production of antistreptococcus serum.

PREVALENCE OF HEMOLYTIC STREPTOCOCCI

	Positive for Hemolytic Streptococci, No.	Per Cent.
Swabs from measles cases	857	35
Swabs from lobar pneumonia	165	69
Sputum specimens from lobar pneumonia	92	41
Swabs from scarlet fever	192	87
Swabs from otitis media	204	74
Swabs from mumps	147	37
Swabs from tonsillitis cases	79	54
Cultures from removed tonsils	142	82
Nose swabs from carriers	69	55
Average percentage of streptococcus carriers among foregoing cases	...	59
Throat swabs from average healthy individuals	168	6
Total	2,135	

The clinical classification of the pneumonias is important, though less so than the classification from the bacteriologic point of view. From the findings here presented it would seem that the disease may be classified according to the causative organisms into two main groups, secondary streptococcus or pneumococcus pneumonia following virus infections and primary pneumococcus which may be followed by secondary streptococcus pneumonia.

We confirm the contention of Smith and Brown that the hemolytic streptococcus Type III hemolysis is a definite type, in that the colonies produced by us in 10 per cent. horse blood agar were uniform in character, and that 150 strains secured from necropsies, throat swabs, and sputum specimens gave the characteristic sugar reactions. Since the hemolytic streptococcus has proved to be such a common cause of death, in the accompanying tabulation we present in brief the percentages of prevalence of this organism in the 1,967 specimen examinations.

It is interesting to note that nose swabs were taken from sixty-nine known carriers, and that 55 per cent. of these proved positive for streptococci. This finding, in conjunction with our experiments showing that streptococci in droplets are forced into the air during the act of coughing, might lead one to believe that droplets as well as indirect contact infection would be a serious problem in measles and scarlet fever wards. To gain some information on this point, the dust from seven wards was examined, with negative results. Although ward dust may be quite free from streptococci, yet our observations in the surgical wards would indicate that bed linen and garments soiled with streptococci may act as a transmitting agent in the case of wound infection. Among clean operative cases the wounds in twelve became infected with hemolytic streptococci. Throat swab examiners showed that all these patients were streptococcus carriers. Auto-infection, either through soiled linen as a medium or through the blood stream, would in these cases appear to be the only two avenues of infection; and of the two, the former would seem to be the more possible.

From the results of throat swab examinations of twenty-eight attendants in the streptococcus wards, it was found that 25 per cent. of these were hemolytic streptococcus carriers. If this finding alone is considered, one would conclude that streptococcus pneumonia may be called a hospital infection. But this is not so, because it was shown that 94 per cent. of all streptococcus pneumonia patients were streptococcus carriers on entrance to the hospital. In addition, it was found by the examination of convalescent measles patients that streptococcus infection rarely occurred in the hospital wards. Infection of ward attendants is naturally the result of prolonged exposure and close association, and from the results of our investigation it would seem that cross-infection among patients seldom occurs. In order to prevent the possibility of cross-infection in the wards, which we do not believe takes place to any great extent, patients harboring hemolytic streptococci should be isolated as soon as possible after admission.

In the large cantonment hospitals where a large number of patients are cared for, it is preferable to have three or more wards—one of these used exclusively for a detention ward, where regulations providing for the sheet method of separation, the individual face mask, and the frequent washing of hands of attendants are rigidly enforced; other wards may be designated as streptococcus and clean wards.

In the streptococcus wards, the usual methods of disinfection and the practice of scrupulous cleanliness of hands should be insisted on in order to protect attendants against infection. In our opinion, the sheet and individual mask method of protection is of value only in the detention ward, or when it is impossible on account of lack of laboratory facilities to classify the patients into carriers and noncarriers.

CONCLUSIONS

From the evidence here presented it will be seen that:

1. The hemolytic streptococcus was present in the throats of 35 per cent. of all measles patients on entrance to the hospital, and that 94 per cent. of measles patients who developed bronchopneumonia belonged to this group of carriers, while only 6 per cent. of noncarriers developed pneumonia complications.
2. This streptococcus was found in pure cultures at necropsy in the serous cavities and heart's blood of all measles-pneumonia patients, and in 55 per cent. of lobar pneumonia patients.
3. This streptococcus is the same as the beta streptococcus of Smith and Brown.
4. Type III hemolytic streptococci isolated from the serous cavities and heart's blood were always large zone hemolyzers.
5. The presence of hemolytic streptococcus in the throat and sputum of so-called lobar pneumonia patients and in the serous cavities and lungs at necropsy shows that in the classification and treatment of the pneumonias, the streptococcus must be as diligently sought for as the type pneumococci.
6. Laboratory men should acquire a technic for the recognition and isolation of the hemolytic streptococcus from throat swabs and sputums of measles and all pneumonia patients.
7. In practically all cases (94 per cent.), the hemolytic streptococcus is acquired *before* entrance to the hospital.

Prevention consists in: (*a*) the pasteurization of all milk supplies, thus eliminating the possibility of septic sore throat followed by the carrier state; (*b*) the removal of tonsils of those individuals who are identified as streptococcus carriers; (*c*) the control of measles epidemics by the early recognition and isolation of patients; (*d*) the segregation of streptococcus carriers in hospital wards; (*e*) scrupulous cleanliness of the hands of attendants and patients, and (*f*) the development of a reliable vaccine and serum treatment.

TWO NEW DIAGNOSTIC METHODS FOR PATIENTS WITH CARDIAC DISEASE

JULIEN E. BENJAMIN, M.D. (Cincinnati)
AND
ERNEST R. BROOKS, M.D. (Cleveland)
Captains, M. C., U. S. Army; Members, Cardiovascular Board
CAMP FUNSTON, FORT RILEY, KAN.

1. TACHYCARDIA

In the recent articles on the subject of so-called soldiers' heart, latterly termed "neurocirculatory asthenia," it is noted that this syndrome is encountered in the civilian as well as in the soldier. This fact is borne out forcibly if one is on the alert during the entrance examinations of recruits. Since the beginning of the very large draft increments, every man entering the service has been examined for evidence of cardiovascular disease. This work, formerly done parenthetically by the tuberculosis board at Camp Funston, is now conducted by medical officers of the cardiovascular board, who have had a rare experience in examining many subjects and in the detection of suggestive signs of cardiovascular disorders. At an average, during a large draft, 1,500 men pass through their hands each day. Two medical officers, working in shifts of two hours each, are responsible for this work. From 5 to 7 per cent. of the total number (1,500) each day are referred to the cardiac room for suspected cardiovascular disease. This room is manned by two officers. Here the subjects have a searching examination, the results of which are recorded, if necessary.

The most difficult and trying task in the preliminary examinations is the proper decision in cases showing various grades of tachycardia. They represent an enormous number of cases. When one considers that at this receiving station, which represents a highly organized and beautifully regulated machine, the men are admitted, bathed, examined (physically, morally and mentally), inoculated, put into soldier's clothes and assigned, all on the day of their arrival, it is little wonder that even the most stable nervous systems show evidences of psychic disturbance. However, after the observation, in the course of many previous examinations, of certain indefinable, as well as some well defined points, a large portion of these cases are disposed of with little effort. Although it is not a bit unusual to listen to hearts in this category beating between 120 and 180, still in cases of simple or neurotachycardia the accompanying dyspnea is not present. The patients frequently breathe irregularly both as to rate and depth. They are "fidgety" and have coarse, irregular tremors often confined to one hand or the other, stopping during conversation. No pinched expression is noted. There is frequently some hesitancy in speech. The individual is simply excited. Frequently during auscultation the heart gradually reduces its rate to nearly normal, and again accelerates, especially if the patient is allowed to talk or is told to breathe deeply. In nearly all such cases, the dorsal posture causes an early or delayed diminution of the pulse rate to 100 or lower. It becomes second nature to resort quickly to one or the other method of proof of nervous influence. There are, however, a large number of cases which are not amenable to these tests. A very reliable means at our hands for testing for simple tachycardia will presently be advanced.

With the cases of persistent tachycardia (of course, excluding toxic causes), the task becomes quite difficult. This holds true for the soldier as well as for the recruit. It is amazing to note with what rapidity the heart beats, in such cases, with no apparent discomfort on the part of the individual. During inactivity there is no disturbance of respiration. No simple means, as explained before, are of avail in reducing the cardiac rate. The patients are usually not excited. Their response to exercise is poor, prolonged dyspnea, increased tachycardia, returning in from three to five minutes to the original high rate, a somewhat anxious look and inordinate sweating being prominent symptoms. Questions, not leading in character, usually elicit one or more of the following facts: (1) poor sustaining powers in games, running or lifting, dating from some infection, such as rheumatism, grip, pertussis or measles; (2) various types of sensations in the region of the precordium at irregular times, described as a burning, actual pain, or a feeling of fulness or heaviness; (3) palpitation, or a consciousness of rapid heart rate, especially in the recumbent posture; (4) spots appearing before the eyes, and giddiness but seldom actual fainting; (5) headache. It is usually related that one or more of these symptoms always appears during exertion, but may be present during rest. In a few instances, a well defined history of mental or "nervous" diseases in the family is obtainable; but statistics on this point are meager.

Let it be repeated, the same condition exactly is noted in the raw recruit as in the tried soldier. The latter is referred for investigation, because of his inability to stand effort. The former is suspected in the course of examination, owing to a persistent rate above 100. The condition belongs to the neurocirculatory asthenia category. It is interesting to note in such persons how natural forces have guided their footsteps. If they are of the farming class, their work has been facilitated by tractors or riding. In the various civic occupations, they have sifted into positions necessitating little bodily effort.

Now as to the test that has been of such great aid in our work. If the procedure has been suggested heretofore, it is very probable that its use has not been generally appreciated. Its value lies in the fact that the separation of the more stubborn cases of simple tachycardia from the persistent ones is facilitated. The individual, on direction, drops the head and bends forward to about an angle of 45 degrees, whereupon the rapid heart will retard to a remarkable degree very quickly, sometimes to half of the original rate, if the case is one of simple tachycardia. The other type is not affected at all. Also in the former instance, the rate in the bending position corresponds fairly accurately to the rate in the recumbent posture. It requires less time to resume a nearly normal rate in the former than the latter procedure and is, thus, a quicker method. The test has been applied in a very large number of cases so far with very gratifying results. A certain number of soldiers who have responded to this test have been followed up. They are doing full duty.

This adjunct, in the disposition of a rather difficult group of cases, is recommended for further use and comment by members of the service and the profession.

2. AMYL NITRITE INHALATIONS AS AN AID IN THE DIAGNOSIS OF PRESYSTOLIC MURMURS

A probable explanation of the large number of cases of mitral stenosis reported from the various camps is the fact that fatigue, excitement and the influence of new environments cause the heart tones in many instances to become altered in character. The experience at this camp, where large numbers of recruits are examined, bears evidence to this fact. This has been true to such an extent that in our reports to the Surgeon-General, certain new terms have appeared as characterizing diagnoses, such as "blurring of the first mitral tone" or "reduplication of the first sound at the apex." This has been done simply to indicate that there is possibly some disturbance during presystole, but that there were no other signs present of a definite nature. Also, there has been much discussion among the cardiovascular examiners concerning definite thrills felt at the mitral area. By close observation, however, it is the conviction of this board that the time of the thrill, other than those characterizing mitral stenosis (or a similar lesion at another area) is systolic and due to an overacting ventricle. In most instances, a recumbent position, or exercise, causes the systolic thrills to disappear. As suggested above, the same difficulty has been experienced by other observers, and various tests have been suggested as a means of establishing a certain diagnosis, or excluding it.

Our purpose here is to advance the results of our observation in the use of amyl nitrite inhalations as an aid in this difficulty. The procedure was recommended by R. A. Morison.[1] This investigator suggested, after a fair trial of this drug, that a valuable aid was at hand to eliminate the difficulty in the diagnosis of the existence, or nonexistence, of presystolic murmurs. We have followed his method in each instance.

---

[1] Morison, R. A.: Amyl Nitrite Inhalations in Diagnosis of Mitral Stenosis, Brit. M. J. 1: 452 (April 20) 1918.

The division surgeon procured fifty ampules of amyl nitrite, containing 3 minims each. These were used in all doubtful cases. Of course the influence on the heart, as far as it concerns our experiment, is very similar to the effect of exercise. However, there is one great advantage: It is possible to listen to the heart during its period of increasing activity and acceleration, and there is no attending dyspnea as a disturbing factor. In other words, as the patient administers the drug to himself the observer listens at the apex of the heart until the desired effect of the drug is produced. In this way several phases of increasing cardiac activity are observed. A total of forty-eight cases has been examined, and it is the opinion of the observers that a very valuable aid in diagnosis has been obtained. In ten cases, the doubtful nature of the presystolic sound was intensified to such a degree as to admit of a positive diagnosis of mitral stenosis. In the balance of the cases, the suggestive presystolic sounds were eliminated. It might be said here that the greatest difficulty was experienced in the negro, for here the element of neurosis is clearly manifest, and this influence on the heart produces at times varied changes. Chief among these are a greatly accentuated pulmonic second and a very loud sound at the apex and a thrill at this area, the timing of which is frequently difficult. In such cases we have found recourse to these inhalations valuable.

Naturally a report of this nature partakes entirely of personal experience, as there is no definite way to publish the data. The chief object in presenting our observations is to corroborate thoroughly the findings of Morison, and to suggest the further use of this method.

TREATMENT OF INFLUENZAL PNEUMONIA BY THE USE OF CONVALESCENT HUMAN SERUM

SECOND REPORT

L. W. McGUIRE, M.D.
Lieutenant-Commander, M. C., U. S. Navy
AND
W. R. REDDEN, M.D. (Boston)
Lieutenant, M. C., U. S. Navy
CHELSEA, MASS.

In a preliminary report,[1] we presented the data of thirty-seven cases of bronchopneumonia, following the present epidemic of so-called influenza, treated with serum obtained from patients who had recovered from a similar pneumonia. Later, in an informal letter to The Journal, we[2] advised the discontinuance of the compatibility tests, and other modifications to simplify the preparation and administration of the serum.

The present report gives as complete data as were obtainable in 151 cases at the Naval Hospital, Chelsea. This represents all cases of the foregoing type admitted to our wards since the treatment was started. For convenience and completeness, this includes the original thirty-seven cases reported.

In our preliminary report, we also noted that the severity of the disease was on the wane. Naturally, we wished for an opportunity to carry on the work in a field in which the severity of the epidemic was unquestionably great. After several futile attempts to find such a place, there came to us a group of men from the U. S. S. *Yacona*. Here the incidence of the influenza, the complicating pneumonia and the severity of the infection appeared quite comparable with the situation at the beginning of the outbreak. Hence, for comparison, we have considered this group not only in the 151 total cases, but also separately. In addition to this *Yacona* group, it should be noted that eighty cases represent the latter part of the first epidemic, whereas the others represent those in the more recent recrudescence of the epidemic where the severity of the disease has undoubtedly been great, though somewhat less than during the first part of the epidemic. Furthermore, also for the sake of completeness, we are presenting the entire laboratory and clinical procedure.

TABLE 1.—DAY OF PNEUMONIA WHEN SERUM WAS FIRST GIVEN, AND NUMBER THUS RECEIVING IT

Day	No.

Total	151

The accompanying tabulations represent in detail our findings in the cases treated.

The day of the pneumonia on which the serum was first given in the 151 cases tabulated is indicated in Table 1. It is evident that most of the patients received serum within the first four days of the pneumonia, and that the majority received it within the first forty-eight hours. In other words, although most of the patients were seriously ill, they received serum within a time most favorable for serum therapy.

The number of injections of serum each patient received is shown in Table 2. It will be seen that three injections of serum were sufficient in 132 cases, and that more than two thirds required only two doses and that about one third required only one dose. It is noteworthy that the majority of the patients requiring more than one injection had advanced at least two days in their pneumonia.

The average amount given at each injection was 120 c.c.

IMMEDIATE RESULTS

A chill, as described below, may follow in thirty minutes after injection of the serum. In a few hours, the patient shows decided signs of improvement. The toxic symptoms subside, as indicated by cessation of nausea and vomiting, if present, and disappearance of vasomotor disturbances and headache. The anxious expression of a sick patient is transformed into that of a patient in convalescence; these patients say that they are decidedly better, and often that they are well. The temperature, pulse and respiration begin to fall, the temperature and pulse reaching normal in advance of the respirations. The appetite returns. Signs of improvement or recovery may follow the first injection of serum, or in severe cases a gradual improvement may take place. Two or more injections may be necessary to produce these results, as indicated in the preceding tabulations.

TABLE 3.—PERSISTENCE OF FEVER AFTER FIRST INJECTION OF SERUM

	No.
Normal less than 24 hours	27
Normal in 24 hours	56
Normal in 2 days	38
Normal in 3 days	14
Normal in 4 days	8
Normal in 6 days	3
Normal in 9 days	1
Normal in 11 days	1
Total	148

Of 138 patients, eighty-three recovered by crisis and fifty-five by lysis. As crisis we have considered a drop of temperature to normal within twenty-four hours, accompanied by a corresponding general improvement. A more gradual decline in signs and symptoms we have called lysis.

A summary of the number of days the fever persisted after the first injection of serum is given in Table 3, which represents 148 patients who recovered from influenzal pneumonia. Three of this group later developed a hemolytic streptococcus bacteremia and empyema, followed by death. The other three necessary to make our group of 151 cases represent the deaths.

As indicated above, the greater number became normal within forty-eight hours after the first injection of serum.

Total*	145

* There were six deaths.

The total febrile period of the pneumonia in this series of cases is given in Table 4. It will be noted that seventy-two, or 51.7 per cent., of this number ran a pneumonia course in three days, and that 119, or 85.6 per cent., were normal in five days. This is a decided shortening of the disease.

The length of time the lung signs persisted, after the temperature remained normal, varied as to the amount of lung involvement and the time in the pneumonic complication when serum was administered. Those cases in which serum was given early in the disease, before extensive consolidation occurred, cleared more readily, while in those treated later in the disease, the physical signs remained a week or ten days and in some cases beyond that period. A striking feature in many cases is the persistence of the signs of consolidation during convalescence.

In several cases that are not included in the 151 reported, serum was given before definite signs of consolidation appeared. That is, only râles were present, accompanied by a high temperature, following influenza. These patients promptly recovered and did not develop consolidation, and it is believed that pneumonia may have been prevented.

The data on white blood counts taken on the group are incomplete. We attempted to have such counts in all cases, but when we came to tabulate, we found that in the early part of the work a number had been missed. However, this group represents 130 cases (Table 5). It is quite evident from this table that the vast majority of our influenzal pneumonias have had either a normal white blood count or a leukopenia. The extra twenty counts represent additional counts in a number of the cases.

Total	108	42

It is noteworthy that all cases that did not respond readily to serum treatment were included in the group having high white counts, although many with high counts did respond readily. The foregoing group of high counts also includes all who showed the hemolytic streptococcus complication. Our differential counts show some tendency toward an increase in lymphocytes and a corresponding decrease in polymorphonuclear leukocytes; but there is no constancy in the findings.

It has been our custom to consider all patients with physical signs of pneumonia and a white blood count of 10,000 or 12,000 or under, as presumptive influenzal bronchopneumonias, and to start convalescent serum treatment immediately, especially if the history of onset is suggestive. But, if the count is higher, typing of sputum is done. Even if the count is high and pneumococci of Group IV are present, the convalescent serum is given with the idea that the Group IV may represent only a part of the infection or even only a mouth organism.

Complications were infrequent. One patient developed acute otitis media. One had intense jaundice, lasting over a week. Three had pleurisy, one phlebitis and two an evident relapse after an apparent complete recovery. Since the recurrence of the epidemic, among the last cases, seven streptococcic infections followed;

these were similar to the streptococcic pneumonias and empyemas present last winter. Six of these patients developed a streptococcic empyema, three of whom died. A pure culture of streptococci was obtained from the blood of one of the other patients. These streptococcic infections followed when the patients were convalescing from influenzal pneumonia, a normal temperature of from two to four days being present in the interval. This accounted for three of our deaths.

OUTBREAK ON THE YACONA

The U. S. S. *Yacona* left Bermuda, November 5. Influenza was epidemic, but reported to be well in hand there at that time. Eight hospital corpsmen of the Navy came North aboard the *Yacona* as passengers, having been on duty in Bermuda, assisting in the epidemic of influenza. They were left at New York. The ship arrived in New York on the 11th; liberty was granted; coal and provisions were taken on, and the ship sailed on the 15th for New London, arriving the same day. The first case of influenza developed in New London on the 18th, another on the 19th, and the third on the 20th. The ship sailed for Halifax on the 21st; six cases developed that day and she put into Boston, arriving the 22d.

Fourteen cases of influenza were admitted to the Naval Hospital, Chelsea, November 22; eighteen on the 23d; nineteen the 24th; nineteen the 25th; five the 26th, and two the 29th, a total of seventy-seven, plus three at New London, making a total of eighty cases of influenza from a crew of ninety-six. Seventy-four men and six officers developed the disease, or 83.3 per cent.

It seems probable that the source of infection was at New London, as the first case appeared three days after arrival there; this was well within the incubation period.

This outbreak was virulent, resembling the cases admitted during the early part of the epidemic in Boston. The patients were admitted with high fever, prostration, headache, injected eyes, dusky skin, albuminuria and low white blood counts.

The severity is well illustrated by the one death that occurred three days after the initial symptoms of influenza. The patient died of a diffuse bronchopneumonia, living only twelve hours after admission to the pneumonia ward, he being then semiconscious, with temperature, pulse and respiration very high. This is the shortest course of the disease of which we have record in this hospital.

TABLE 6.—SUPPLEMENTARY REPORT OF CASES OCCURRING ON THE U. S. S. YACONA

	No.

Officers	9
Total	96
Influenza cases	80
Bronchopneumonias	20
Deaths	1

Of the seventy-seven patients in this hospital, twenty developed pneumonia. All pneumonia patients received convalescent human serum immediately when a diagnosis of bronchopneumonia was made. Every influenza patient was examined at least daily to detect a beginning pneumonia, and twice daily if the temperature remained high beyond the second day of the influenza. One patient had a complicating Type I pneumococcus for which the appropriate serum was given. Two patients, after a prompt subsidence of the influenzal pneumonia, developed a streptococcic lung infection; one was complicated with empyema. These secondary invaders follow in the path of the influenzal pneumonia and are to be expected.

We believe that the low mortality was directly due to the use of convalescent human serum, as the patients immediately improved and rapidly recovered after its use: the serum was efficacious in this group of severe cases.

METHOD OF FOLLOWING CASES

The diagnosis of pneumonia in every case was made by at least two clinicians, and, in the majority of the cases, the diagnosis was confirmed by Dr. F. Van Nüys, Lieutenant, junior grade, U. S. N. R. F., one of the senior members of our medical staff, who was called in as a disinterested observer. Daily notes were dictated to a Red Cross worker in every case till the patient was convalescent. From these notes, from the laboratory reports and from the temperature charts, we have collected our data. The following is a statement from Dr. Van Nüys:

> Up to October 9, I treated pneumonia patients according to regular methods, with good nursing, fresh air, hydrotherapy and symptomatically with drugs.
>
> On the above date, I took clinical charge of that ward wherein serum treatment was being used.
>
> The contrast between the results of the two methods of treatment was very striking.
>
> In a ward under the old treatment, the atmosphere was predominately tragic—many patients desperately sick, cyanotic, dyspneic, coughing and often in agony. The convalescents were subdued by suffering about them.
>
> In the serum ward the atmosphere was that of hope and cheerfulness. A few patients were quite sick, but usually comfortably so. The rest practically convalescent.
>
> These contrasting pictures are fixed indelibly in my mind.
>
> With the old treatment, my mortality figures were close to 28 per cent.—identical with those of another pneumonia ward under Dr. Joseph A. Meledy.
>
> With the serum treatment, mortality was practically nil, except in those pneumonias entering too late for early use of serum.

PROCEDURE

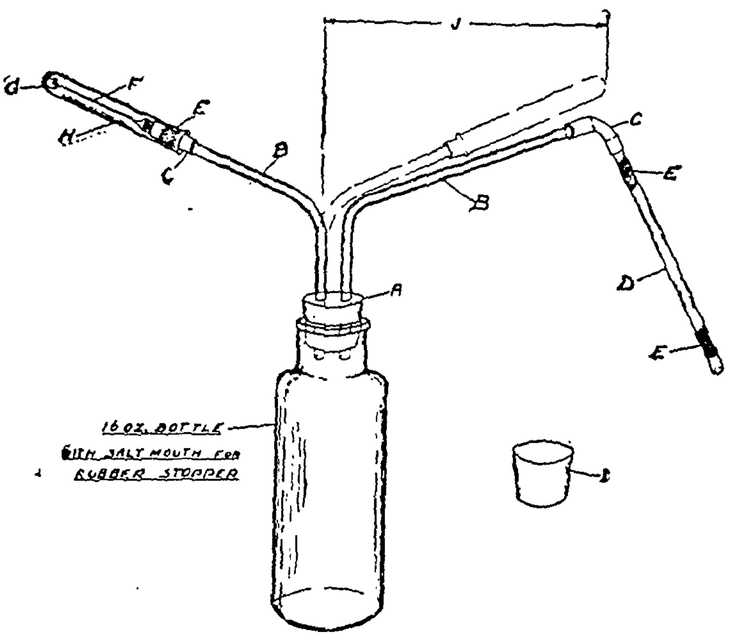
Routine Wassermann tests are done on all patients admitted with pneumonia so that by the time for bleeding there is no delay. In outside practice, blood is obtained at the time of the first injection of serum.

The amount of blood obtained from each donor totals about 1,000 c.c.; that is, about 500 c.c. are taken at two succeeding bleedings, at an interval of a day or two. No untoward symptoms aside from slight faintness in two or three have ever occurred in a series of over 500 donors, so we believe that 500 c.c. are well within the limits of safety in an adult weighing 120 pounds or more. Most patients seem to feel better after the bleeding, especially in the matter of an increased appetite.

The time of bleeding after temperature reaches normal has been set at about ten days. However, we have bled even earlier than this. For an upper limit, we have considered about six weeks. Naturally, this is arbitrary in the absence of any method of titrating the serum. However, at one time, we were short of serum and were compelled to use that obtained from men who had been well for from six to eight weeks. We were impressed with the lowered potency of this pooled serum.

The apparatus for obtaining blood, as shown in the accompanying illustration, is wrapped in cloth and autoclaved. Negative pressure is produced either by an assistant sucking on tube *E*, or by connecting an aspirating bottle to *E*, with a tourniquet adjusted on the donor's arm so that the pulse is still palpable; there is usually no difficulty in getting the desired amount. At times, especially if the donor has not been up, there is a collapse of the vein over the end of the needle. This is due chiefly to an improper adjustment of the tourniquet or too much negative pressure or both. This can frequently be remedied by having the donor open and close the hand. In obtaining blood from men, there is usually not enough discomfort to require the use of a local anesthetic, but in women, it is advisable to inject a little 1 per cent. procain at the point of proposed puncture. An equipment should include about ten complete bleeding sets with a dozen extra bottles. For centrifugalizing, 50 c.c. or larger tubes are advisable.

Preparation of Serum.—The blood is allowed to remain in the incubator at body temperature for an hour shortly after it is collected. By this time, if one is pressed for serum, he can obtain about 100 c.c. from each 400 or 500 c.c. of blood; otherwise the blood is placed in the refrigerator for from five to six hours, or over night. Then the serum is decanted and centrifugalized to clear it of any bits of fibrin or red cells, etc., after which all the serum obtained is pooled. To this pooled serum are added 20 c.c. of 1.5 per cent. tricresol made up in physiologic sodium chlorid solution for every hundred c.c. of serum so that the tricresol content is about 0.3 per cent. The serum is then stored in 120 c.c. amounts. Serum prepared this way has been used with excellent results six weeks after storage. Frequently what appears to be fat accumulates on the surface of the serum; this goes into solution on heating to body temperature, and apparently is of no significance.



Bleeding apparatus: *A*, two hole rubber stopper K-33; *B*, glass tubing; *C*, rubber tubing; *D*, glass tubing for suction; *E*, cotton plugs; *F*, 18 gage needle; *G*, stylet; *H*, small test tube; *I*, blank rubber stopper K-33; *J*, the left tube turned for convenience in sterilizing.

We formerly carefully took cultures of all serum before tricresolizing, but when we found no positive cultures of possible contaminating organisms in 200 serums, we considered the procedure sufficiently sterile to warrant the omission of cultures.

The amount of serum obtained from 500 c.c. of blood varies from 175 to 225 c.c. This seems to represent about the serum content of that amount of blood so that there is little, if any, waste of that part of the blood which contains all or most of the antibodies.

Administration of Serum.—We have found it convenient to give the intravenous injection of serum by means of a 120 c.c. glass syringe, or by the use of a 50 c.c. Lüer syringe connected to a three-way cock and proper tubing, as used in administering arsphenamin. Rarely does the procedure occupy more than ten minutes. The serum is first warmed to slightly above body temperature. We have given as high as 250 c.c. in one dose.

SERUM REACTIONS

While we were doing compatibility tests, four patients had chills lasting from ten to thirty minutes, coming on about thirty minutes after the administration. These chills on the whole were less severe than those following horse serum. Since the discontinuance of the compatibility tests and the pooling of serum, the percentage of chills has been about the same or less. There is usually a rise in temperature, pulse and respiration, shortly after the injection, but never any sign of anaphylaxis. Never have we seen urticaria at any time after the use of human serum, or other signs or symptoms of serum sickness.

It has been our desire, from the beginning, to run parallel control groups without serum treatment, with treatment by use of "normal" human serum, and with treatment by use of serum from those having had influenza without lung complication. For obvious reasons, we were unable to allow patients with the pneumonia complication to go without serum treatment. However, it seemed justifiable to give some men one dose of serum from normal individuals, or from those recovering from influenza alone. Again, we were unable to complete the experiments but were able to get suggestive evidence. The patients chosen for the experiments were taken at random from the groups as they were admitted. The results are reported for what they may be worth.

Incomplete experiments were conducted with pooled serum from men who never had influenza, so far as we could find. Serum was obtained from ten so-called "normal" donors. This was pooled and tricresolized, and then 100 c.c. were given to five influenza patients admitted to the ward. At the same time, three other patients taken at random received 100 c.c. of the "anti-influenza-pneumonia" serum. The next day, all who had received the "normal" serum showed the same or a higher temperature, while the three receiving the same dosage of anti-influenza-pneumonia serum showed a drop of temperature to normal. Unfortunately for scientific accuracy, we were compelled to give the anti-influenza-pneumonia serum to the other five patients instead of continuing treatment with "normal" serum. The five showed normal temperatures after the first injection of the anti-influenza-pneumonia serum. We feel that this is suggestive, but not conclusive, though it corresponds with similar experiments earlier in the epidemic.

Incomplete experiments were conducted with pooled serum from men who had influenza and who never showed definite consolidation. Serums from five such patients were pooled and tricresolized, and a 100 c.c. dose was given to each of three patients sent to the pneumonia ward. Two others were given an equal dose of immune serum. Two of the first group showed slightly higher temperature the next morning; one showed a drop of 2 degrees. The two receiving the immune serum showed a normal temperature the next morning. On further examination, it was found that all had a definite area of consolidation except the man receiving "normal" serum, whose temperature fell 2 degrees. The first two showed a normal temperature sixteen hours after the injection of 100 c.c. of immune serum. Here again evidence is incomplete, but suggestive, as noted in the previous article.

In addition to the foregoing experiments, it was early noted by us, when serum from single patients was being used, that certain serums had no measurable effect. On further investigation, it was invariably found that such serums came from men who had only a small lung involvement, or had only a small involvement and had recovered rapidly under serum treatment, or else had been obtained from individuals in whom the disease had run a long course with a swinging temperature and an increasingly high white count. Because of earlier findings in a few mild cases treated with serum, we were led to state that patients who had received serum did not yield potent serum. However, recent experience has demonstrated that serum from such patients has potency equal to that from untreated patients.

COMMENT

From the data presented, it is evident that a low white blood count is characteristic of the usual bronchopneumonia following influenza. Hence it is of prime importance before serum therapy is instituted. In our experience, a low respiration and low pulse rate, compared to the lung involvement and high temperature, aid in making a diagnosis of influenzal pneumonia.

At present, the only method of testing the potency of the convalescent serum is by its effect on the patients. In our observations here, it would seem that one of the first reactions is against toxic symptoms, such as nausea, vomiting, vasomotor disturbances and loss of appetite, so that it might be safe to say that the serum has some antitoxic action. Beyond this, we believe that discussion at the present time would be futile.

The method of obtaining and administering the serum has been reduced to its simplest form, so that little difficulty need be experienced in establishing the treatment, at least in centers. At the present time we would suggest the establishment of bronchopneumonia wards in various hospitals, with one man in charge of the serum treatment. Then by starting with four or five donors recently recovered from the disease, sufficient serum can be obtained to institute treatment. This, once started, can be continued, provided sufficient interest is taken in the procedure. We are convinced that the results will fully repay one for the effort.

That the tricresol is not an important factor in the results obtained is evidenced by the fact that no difference has been noted in the action of the preserved and unpreserved serum.

Influenza patients who have a continuous high temperature persisting over three days, or who have a secondary rise of temperature immediately following influenza, should be regarded as probably developing influenzal pneumonia. Signs of consolidation may not be present at this time, but patches of fine râles can usually be found. These signs, taken in conjunction with a persistent low white blood count and in the absence of other complications, almost invariably mean a beginning influenzal pneumonia. This is the most favorable time to start serum therapy. If serum is given at this early stage of pneumonia, favorable reaction is universal. If one depends on a rising pulse and respiration, as well as on the high temperature, he will frequently allow a patient to pass beyond the time most favorable for any kind of serum therapy.

SUMMARY

Out of 151 patients with bronchopneumonia following influenza treated by human convalescent serum, three have died without complications, and three have died after a complicating hemolytic streptococcus empyema, making a total of six deaths, or 4 per cent.

Most of the cases were treated early in the pneumonia complication, and hence were well suited for serum treatment.

Out of 151 patients, 132 received three doses of serum or less; about two thirds required only two doses, and over one third but one injection. Those who received more than one injection for the most part had advanced to at least two days in their pneumonia. The average dose used here is 120 c.c.

Out of the 138 patients, eighty-three recovered by crisis, and fifty-five by lysis.

In 148 cases, over half showed a normal temperature within forty-eight hours after the beginning of serum treatment.

The febrile period of the disease was decidedly shortened, though the lung signs persisted.

Several cases without definite signs were treated with serum. These are not included in the group reported. In some of these cases, it would seem that possibly a pneumonia was prevented.

Incomplete experiments with pooled "normal" serum and with pooled serum from uncomplicated influenza patients indicate a lack of curative power in such serums. Pooled serum from patients treated with immune serum seems to have about the same potency as that from the earlier untreated cases.

Over half the cases treated were received during the recent recrudescence of the epidemic, when there has been no doubt about the severity of the pneumonia complication. Complications have been infrequent.

There has been no increase in chills since the compatibility tests were discontinued. We have never seen urticaria or any other signs of serum sickness after the use of human serum.

Bronchopneumonias with a white blood count below 10,000 or 12,000 are most favorable for treatment with this serum, though a number with much higher counts responded readily.

CONCLUSIONS

Pooled serum from convalescent influenzal bronchopneumonia patients at this hospital has greatly reduced mortality, has shortened the course of the disease, and has proved almost a specific, not only during a waning epidemic but also during the more recent severe recrudescence.

U. S. Naval Hospital.

Treatment of Chronic Asthma.—Dr. M. Machado emphasizes the necessity for putting an end to the predisposition which brings on the attacks of true asthma. This constitutional predisposition is best combated, he has found in his experience, by iodid and emetin. "The iodid acts on the structure and functioning of the cells while the emetin regulates the apparatus of the internal secretions. The two combined break up the diathesis which is responsible for the asthma." He gives the emetin by injection of 0.04 gm., increasing by 0.01 gm. a day until the dose is 0.08 gm.—a total up to 0.30 or 0.38 gm. in the course of five or six injections. After this he gives a course of sodium iodid by intravenous injection of 20 c.c. daily or on alternate days, increasing by 10 c.c. each time until the 100 c.c. dose is reached. From twenty to thirty injections may be required to overcome the chronic tendency to asthma. It only gradually subsides. There has never been recurrence in any of his cases thus treated; in some the interval since has been three years. His communication appeared in the *Gazeta Medica da Bahia,* **50**:97 (September) 1918. No further details of the technic are mentioned.

MENINGEAL CONDITIONS NOTED DURING THE EPIDEMIC OF INFLUENZA

JOSEPHINE B. NEAL, M.D.
In Charge of the Meningitis Division, Bureau of Laboratories, Health Department
NEW YORK

In reviewing the cases of meningeal involvement developing during the epidemic of influenza, my attention has been drawn to three points:

1. Very few cases of meningitis have been due to the influenza bacillus. I have seen two cases, and have examined the fluids of a third. In previous years, I have seen as many in an equal length of time. If this epidemic was due to the influenza bacillus, it seems strange that it did not more frequently invade the meninges.

2. During October and the early part of November, I saw a larger number of cases of epidemic meningitis than is usual at that season, and the number dropped off subsequently. The great majority of these cases gave a history of an attack, clinically influenza, immediately preceding the development of the meningitis. In some instances, the meningitis appeared as the influenza was subsiding, in other instances after convalescence was established. The cases themselves were not unusual in any way. Some were mild and some severe—about as the cases usually run. Cultures of the spinal fluids were made on blood as well as on glucose ascitic agar to see if any hemoglobinophilic bacilli were present with the meningococci, but there was no evidence of a mixed infection.

Whether the resistance of the individual, both generally and locally in the mucous membrane of the nasopharynx, was lowered by the attack of influenza, thus making him fall more readily a victim to meningitis, or whether the meningococcus attained a heightened virulence through its association with the causative agent of the influenza epidemic, is a question entirely open to discussion.

3. In about twenty instances, I have seen cases, usually during the convalescence from attacks clinically influenza, in which meningeal symptoms have developed. There were present headache, some stiffness of the neck, Kernig's sign, and extreme apathy and drowsiness—in many ways the picture of an early tuberculous meningitis. Lumbar puncture has revealed a clear fluid under increased pressure. This fluid has shown an increase from slight to marked, in the number of cells, with a preponderance of mononuclears, a well marked increase in the albumin and globulin, a normal reduction of Fehling's solution, and no organisms either by smear or culture. In most instances a Wassermann test has been performed, and in all cases have been negative. Guinea-pigs inoculated with a number of the fluids suffered no ill effects. Such a spinal fluid in no way suggests the invasion of the meninges by a pyogenic micro-organism. The mononuclear cells and the normal reduction of Fehling's solution are practically never present in a pyogenic meningitis. This in addition to the absence of organisms by smear and culture is evidence against a meningitis.

This spinal fluid reaction is quite different from that usually found in meningism occurring in pneumonia, gastro-intestinal conditions in children, and acute infections. In these conditions, while the meningeal symptoms are often more pronounced than in the cases I have been describing, the spinal fluid, with rare exceptions, is normal in the chemical and cytologic constituents. The exceptions referred to occur mainly after severe and prolonged convulsions, in the convulsive type of whooping cough, and in cases in which the puncture has been done shortly before death, the circulation having been depressed for some time. In these instances, the changes in the cytology and chemistry are, as a rule, less than have been found in the influenzal cases. The spinal fluid changes that I have just described are similar to those in cases of poliomyelitis and poliencephalitis. From the spinal fluid examinations and the clinical picture it seems possible that we are dealing with an encephalitis secondary to the influenzal attack. With one or two exceptions, the patients have improved after the lumbar puncture and made a good recovery.

Two cases have been a little different from the others:

One of the patients developed motor disturbance—weakness of the muscles of the feet and some paralysis of the fifth nerve. The spinal fluid showed a very marked increase in the albumin and globulin, and a slight increase in the number of cells. The reduction of Fehling's solution was normal. The gold chlorid curve was 00012455550. The Wassermann test was negative. The condition of this patient completely cleared up.

The other patient showed a good deal of mental disturbance, which has continued for over six weeks. It takes the form of a delirium, developing suddenly at intervals and lasting from ten to fifteen minutes. At other times the mentality is clear. He has had four lumbar punctures, and the spinal fluid has remained practically unchanged. He has a considerable degree of arteriosclerosis, without a greatly increased blood pressure.

Menninger[1] recently described nearly a hundred cases of psychoses following influenza. In his cases the spinal fluids were negative, with one exception.

Three cases recently seen in the Willard Parker Hospital have been of a more severe type than the earlier cases and somewhat different. Two of these patients have shown marked tremor. One of these has been delirious; he is still living. The other showed marked cardiac and respiratory arrythmia suggesting an involvement of the cardiac and respiratory centers. This patient died. The third lies motionless with the limbs rigid, has to be fed by gavage, and his face has the masklike expression described by the English writers in connection with cases which they have been reporting under the diagnosis of lethargic encephalitis. All these cases bear a resemblance to the descriptions given of this condition, which has been somewhat prevalent in England for about a year. The changes in spinal fluids in the cases I have seen seem greater than the changes the English have reported, but they have not done lumbar punctures in all their cases and they do not state at what stage of the disease the punctures were done. Moreover, different workers read chemical and cytologic changes in the spinal fluids differently.

Accounts of lethargic encephalitis have been given by Buzzard[2] and by Hall,[3] and it has been discussed editorially in THE JOURNAL.[4]

LETHARGIC ENCEPHALITIS

PRELIMINARY REPORT

O. L. POTHIER, M.D. (New Orleans)
Major, M. C., U. S. Army
CAMP LEE, PETERSBURG, VA.

Last fall The Journal called attention editorially[1] to a series of small epidemics which had been reported during the spring in England and France and which were characterized by cranial nerve palsies, and fever. The French epidemic presented a mortality of 50 per cent., the fatal cases being due to the involvement of vital bulbar centers. The disease was variously regarded as botulism, poliomyelitis and some new infection, although the bacillus of botulism had not been isolated and there were reasons for doubting its identity with poliomyelitis. The spinal fluid in these cases was spoken of as being normal, and the spinal nuclei were apparently never involved. Of the cranial nerves, those having to do with the extra-ocular muscles were so commonly involved that the disease came to be spoken of as infectious ophthalmoplegia. Besides the third, fourth and sixth, the seventh, ninth, tenth and twelfth were said to be sometimes affected. Other symptoms spoken of as common were nystagmus, tremor, drowsiness, delirium, asthenia, retention of urine and constipation. The Journal also lists in its index a number of articles under the caption "lethargic encephalitis," which describe somewhat similar cases in France, Italy and South America. Drowsiness and coma were prominent in these cases.

At Camp Lee there were recently observed a number of cases which seem to fall into this general category, and it seems worth while to publish a preliminary report, as there is some probability that the disease will become much more widespread. The commonest features observed in these cases are vertigo, diplopia, headache, slight fever and a spinal fluid showing a definite pleocytosis (from 20 to 66 cells) of the lymphocytic type. There have been some variations, which will be noted in the case histories. It is worth while recording that there have been no cases of frank poliomyelitis in this camp. The patients came from widely separated organizations. The only fatal case was the first, which will be reported more in detail.

REPORT OF CASES

Case 1.—*History.*—A corporal, C. O. T. S., aged 23, admitted, Oct. 23, 1918, had had an attack of influenza six weeks previously. October 28, he had noticed diplopia and some difficulty in swallowing. He was conscious, rational, and febrile except for part of one day. Of the cranial nerves there was bilateral involvement of the third, sixth, ninth and twelfth. There was no spasticity, and the reflexes and sensation were normal. The eye grounds were normal except for slight engorgement of the veins. Physical examination was otherwise negative. The pulse was slightly accelerated (averaging 90). Leukocytes, October 30, were 9,200; polymorphonuclears, 58 per cent.; lymphocytes, 30 per cent.; large mononuclears, 10 per cent.; transitionals, 2 per cent. The spinal fluid, October 30, was sterile, with 85 cells per cubic millimeter; the globulin test was negative, sugar present, Wassermann test negative. The blood Wassermann was ± (there was no history of infection). The patient showed intermittent difficulty in breathing, and died, November 2, of respiratory failure.

Necropsy.—Opening of the spinal canal disclosed the cord with its membranes lying in the spinal canal without distortion or bulging of the meninges. When the membranes were opened, the blood vessels of the posterior surface of the cord were found tortuous and filled with blood; but the surface of the cord, and the membranes, presented no sign of inflammation. There was no exudate nor excessive fluid in the meningeal space. This description of the cord applies to the different areas of the cord, including the upper cervical region. On section of the cord in the cervical region, on gross examination, there was apparently no change in the cross section of the organ. As one reached the middle dorsal region, going down to the lumbar region, the cord was found to be very much softer, especially in the middle dorsal region. This became less marked as one went down the cord toward the lumbar region. These changes may have occurred postmortem, as they were noted in the most dependent portion of the cord.

On removal of the skull, the dura remained adherent to the calvarium. The hemispheres presented no thickening of the pia mater, but the vessels were very much engorged and arborescent over the convolutions. On removal of the cerebrum, the base of the organ presented the same appearance as the surface; the vessels were arborescent, and there was no thickening of the pia and no exudate.

The pituitary body and the optic chiasm presented nothing of note.

On section of the hemispheres, the centrum ovale presented dilatation of the blood vessels, which appeared as small, punctate bodies throughout the surface. On inspection, the corpus callosum appeared normal; but on attempt to section, it was found to be soft and mushy. All the tissues of the lateral ventricles were soft. The optic thalamus was softened. The velum interpositum and the choroid plexus presented the same condition as the vessels of the surface of the brain: that is, the vessels were prominent, tortuous and arborescent. There was no excess of fluid in the ventricles, but all the tissues surrounding them were softened, the brain substance as well as the tissues of the floor. The third ventricle presented nothing of note, except general softening of the tissues of the floor. The pineal gland was swollen. The iter a tertio ad quartum was patulous. On section of the basal ganglions a small hemorrhagic spot was found in the right hemisphere immediately adjoining the internal capsule. This spot was about 1 mm. in diameter. On the left side, the basal ganglions presented nothing of note. Anteroposterior sections through the hemispheres presented nothing of note. Sections through the cerebellum presented nothing of note. There was, however, a universal softening of the brain tissue which made it very hard to section without destroying it in the attempt. After sectioning, the organ was apparently collapsed, and there was no possibility of returning the sectioned portion back to the former relation on account of this softening.

The dura through the base of the skull was glistening and smooth, and presented nothing of note.

The findings otherwise were negative.

Case 2.—A first lieutenant of Company D., Sixty-Second Infantry, aged 26, admitted, Dec. 24, 1918, had had an attack of influenza two months previously. For two days he had noticed diplopia, headache, anorexia and constipation. He stated that he had sometimes had diplopia before when his digestion was out of order. Examination disclosed weakness of the right sixth nerve, and absence of the cremasteric and right plantar reflexes, but otherwise was neurologically negative. The next day the plantars were normal and there was some increase of the biceps and right knee jerk. There was fever with a maximum temperature of 102, for four days, by which time the patient felt well. The urine was negative, leukocytes, December 24, 8,550; polymorphonuclears, 45 per cent.; lymphocytes, 43 per cent.; large mononuclears, 6 per cent.; eosinophils, 4 per cent.; basophils, 2 per cent. The spinal fluid, December 26, showed 4 cells per cubic millimeter; the globulin test was negative; sugar was present.

The transient sixth nerve palsy with fever seems to justify the inclusion of this case in the series, in spite of the negative spinal fluid and history of previous trouble with vision.

Case 3.—A private of the 305th Fire and Hose Company, Q. M. C., aged 31, admitted, Jan. 18, 1919, had had influenza in October, 1918. He noticed diplopia the day before admission, and complained of headache, vertigo and constipation. There was slight fever for twelve days, with gradual clearing up of symptoms. Neurologically the examination was negative except for sixth nerve palsy, and nystagmus. The urine was negative. The leukocyte count, February 4, was 7,200; polymorphonuclears, 67 per cent.; lymphocytes, 24 per cent.; large mononuclears, 8 per cent.; esinophils, 2 per cent. The spinal fluid, February 4, showed a slight increase of pressure, 20 cells per cubic millimeter; 88 per cent. lymphocytes, and 12 per cent. large mononuclears. The globulin test was negative; sugar was present; the Wassermann test was negative.

SPINAL FLUID

Case	Day of Disease	Cells	Lymphocytes	Large Mononuclears	Polymorphonuclears	Globulin	Sugar	Wassermann
1	3	85	..	..	..	minus	plus	minus
2	4	4	..	..	..	minus	plus	
3	18	20	88	12	..	minus	plus	minus
4	15	64	93	5	2	minus	plus	minus
5	15	40	74	26	..	minus	plus	minus
6	10	66	92	8	..	minus	plus	minus
7	4	7	..	..	..	minus	plus	minus
8	15	29	92	8	..	minus	plus	minus

Case 4.—A corporal, Company 6, Second Battalion, D. B., aged 23, admitted, Jan. 23, 1919, had acute otitis media, January 1, which had completely healed. For four days he had complained of diplopia and vertigo, and later of nervousness, insomnia, weakness and constipation. The retinal veins were swollen and the left disk blurred. There was no evident defect in muscle balance when examined; the knee jerks were exaggerated and later transient, but there was well marked ankle clonus. Otherwise the neurologic examination was negative. There was slight fever for ten days, which gradually improved. The urine was negative. The leukocyte count, February 6, was 7,600; polymorphonuclears, 69 per cent.; lymphocytes, 22 per cent.; large mononuclears, 8 per cent.; eosinophils 2 per cent. The spinal fluid, February 3, showed 64 cells; there were 93 per cent. lymphocytes, 5 per cent. large mononuclears, and 2 per cent. polymorphonuclears. The globulin test was negative; sugar was present; the Wassermann test was negative; the spinal fluid was sterile.

Case 5.—A private, Company 1, First Battalion, I. R. T. C., aged 22, admitted, Jan. 24, 1919, had had influenza in October. For four days he had complained of vertigo, nervousness, insomnia, and "gas in stomach." There was no diplopia. Examination was neurologically negative except for irregular pupils and rather overactive knee jerks. Low fever and vertigo led to lumbar puncture, February 4, which revealed 40 cells per cubic millimeter, 74 per cent. of which were lymphocytes; the globulin test was negative; sugar was present; the Wassermann test was negative. The blood and the urine were normal. The leukocyte count, February 4, was 9,000; polymorphonuclears, 72 per cent.; lymphocytes, 22 per cent.; large mononuclears, 4 per cent.; eosinophils, 2 per cent. Although this patient complained of no diplopia, the vertigo suggests that there may have been some muscular defect, as in the other cases, although not enough to cause double vision.

Case 6.—A private, Company 10, Third Battalion, I. R. T. C., aged 24, admitted, Jan. 31, 1919, a week before admission began to complain of headache, constipation, nausea, diplopia and vertigo. Examination revealed external ophthalmoplegia, overactive knee jerks, and temperature ranging from 98 to 100. The leukocyte count, February 4, was 8,200; polymorphonuclears, 62 per cent.; lymphocytes, 26 per cent.; large mononuclears, 10 per cent.; eosinophils, 2 per cent. Examination of the spinal fluid, February 3, revealed 66 cells; 92 per cent. lymphocytes, and 8 per cent. large mononuclears. The globulin test was negative; sugar was present; the Wassermann test was negative.

Case 7.—A first lieutenant, M. C., of the mustering office, aged 31, admitted, Feb. 3, 1919, four days before admission noticed vertigo, weakness, drowsiness, slight rhinitis, photophobia and diplopia. He also complained of a sensation of "thickness of the tongue." After admission to the hospital no diplopia nor neurologic defects could be made out. The temperature was normal, the urine, blood and spinal fluid, February 3, normal, the latter showing 7 cells per cubic millimeter. There was no globulin; sugar was present. The Wassermann test was negative.

Case 8.—A private, Company I, Sixty-Second Infantry, aged 24, admitted, Jan. 31, 1919, about ten days before admission began to complain of vertigo, and later of weakness and constipation. After admission he was very drowsy, being aroused with difficulty. There was continued high fever; February 3, mild delirium; February 4, difficulty in swallowing, and February 5, left facial palsy. He was still seriously ill. Blood culture was sterile, Feb. 2 and 4. The leukocyte count, February 4, was 7,900; polymorphonuclears, 67 per cent.; lymphocytes, 20 per cent.; large mononuclears, 12 per cent.; eosinophils, 1 per cent. The spinal fluid, February 5, was under increased pressure, and showed 29 cells per cubic millimeter, 92 per cent. lymphocytes, and 8 per cent. large mononuclears.

The eight cases occurred in a comparatively short space of time. They were characterized by a tendency to cranial nerve involvement, fever, and slight changes in the spinal fluid. An increase in their occurrence is to be expected.

VESTIBULAR REACTIONS IN FIVE HUNDRED AND FORTY-ONE AVIATORS

LOUIS LEVY, M.D.
MEMPHIS, TENN.

It is well established that the vestibular apparatus—the internal ear, its nerve pathways and centers—is a mechanism of great importance.

Without dwelling too much on the requirements for an aviator, attention is called to the fact that an excellent physical equipment is demanded of the man who qualifies for flying; hence the rigid examination that is given, which includes the usually accepted methods of examining the vestibular apparatus.

For more than a year, while at work in the Air Service Division, Surgeon-General's Office, I had the opportunity of organizing physical examining units in different parts of the country, which enabled me to study various types of applicants, and at the same time gave me a chance to develop a constant technic in the examining work.

AVERAGE NYSTAGMUS OF FIVE HUNDRED AND FORTY-ONE AVIATORS

Number of Men Examined	Flying Period, Hours	Average Nystagmus	
		Turning to Right Seconds	Turning to Left Seconds
156	0 to 25	25 49/156	25 25/156
169	25½ to 50	25 85/169	25 40/169
59	50½ to 75	19 1/59	18 27/59
37	75½ to 100	24 19/37	25 4/37
21	100½ to 150	25 18/21	25 8/21
34	150½ to 200	26 4/34	25 8/34
32	200½ to 300	23 5/32	23 12/32
14	250½ to 300	23 9/14	25 5/14
19	300½ to 1,000	26 4/19	25 11/19

It is with the vestibular reactions that this paper deals, owing to the amount of discussion in certain articles concerning these tests, and the doubts cast regarding their value. In these papers statements have been made that repeated stimulation, such as experimental whirling or flying, lessens the reactions. If this were so, it would be an important point in considering aviation, because aviators are subject to constant stimulation of the vestibular apparatus during flight. After the aviator had flown for a while there would be no means of judging the condition of this mechanism because of the absence of nystagmus and vertigo; for the loss of these reactions is significant of some impairment of the vestibular apparatus.

With this in view, a series of examinations were made of fliers from Barron, Carruthers and Taliaferro fields. The data presented in the accompanying table are from the first 541 cases examined, the amount of flying varying from that of cadets just arriving to officers who had flown 1,000 hours.

The average nystagmus of accepted applicants from data given by sixty-seven physical examining units showed on turning to the right, 23 seconds and on turning to the left, 23.1 seconds; without dividing this series by the hours of flying, the average on turning to the right was 24.6 and on turning to the left 24.4 seconds. It will be noted that the average nystagmus of the series is slightly higher, probably owing to the fact that there were few fliers examined with less than 20 seconds' nystagmus, while in the examining unit work there were a great many more.

SUMMARY

It is found that nystagmus is not diminished by repeated turnings.

Although vertigo was not timed, past-pointing and falling were slightly diminished in fliers of 100 hours' or more experience, being most noticeable in fliers who have had the greatest number of hours.

As past-pointing and falling are objective signs of vertigo, this diminution was due to the fact that the flier had learned to interpret this vertigo and for the same reason more rapidly recovered his poise.

THE BACTERIOLOGY OF EPIDEMIC INFLUENZA AND PNEUMONIA*

RALPH A. KINSELLA, M.D. (New York)
Major, M. C., U. S. Army
WASHINGTON, D. C.

Perhaps the simplest and most obvious inference that can be drawn from a consideration of the epidemic of influenza that has just passed through this country is that it was something unusual, something that had not been seen for many years, and something that has departed leaving few representative cases that can be regarded as typical instances of the disease. Whatever the cause of the disease may be, it is clear that this agent is one to which the body is not accustomed. In fact, it would almost seem necessary to postulate at the outset that this agent is not commonly present in the body under normal circumstances, because it is difficult to conceive that any bacterium or virus that is even partially adapted to the environment of the human body should suddenly become unadapted and assume such a high degree of invasiveness as the agent of influenza possesses. Moreover, if the cause of influenza is some bacterium or virus related to a variety of bacterium or virus commonly present in normal individuals, then it would seem necessary to postulate that the cause of influenza is a very highly individualized variety.

Without doubt, the epidemic just past is of essentially the same nature as the epidemic of 1889. Then, as in the epidemic under discussion, clinicians recognized two phases or features in the disease: first, the "influenza" proper, which lasted from three to seven days, and the complications which were regarded as secondary and not part of the original disease, though directly due to the damages that it caused. The descriptions of the disease, in England by Robertson and Elkins,[1] in Germany by Strumpell,[2] and in France by Duflocq,[3] make these points clear.

The present report deals with a study of cases of influenza at Camp Lee and Camp Dix. The cases studied at Camp Lee were typical of the disease, the fatal cases being complicated by pneumonia. The studies at Camp Dix were made when the epidemic had abated, and presented more complications, with correspondingly complicated pathologic and bacteriologic findings. A brief description of a typical case at Camp Lee reveals a perfect similarity with the descriptions given in 1889. The prominent features were sudden onset; headache; pain in the back and throughout the body; intense prostration and weakness; signs of conjunctivitis, coryza, sore throat and bronchitis that varied in intensity; scanty nasal and bronchial discharge; fever, and leukopenia. Nosebleed was not uncommon. The conjunctivae were sometimes very red. The throat was usually not markedly inflamed. There were a few cases with barking cough. The most striking symptom was weakness. The conjunctivitis, the bronchial signs and the leukopenia made a case resemble measles—without the eruption. These patients usually recovered in from three to five days, unless pulmonary complications developed.

The object of this study was to determine, if possible, by cultural methods, the bacterial agents operating in these cases. For this purpose, smears and cultures of the nose and throat, in the early cases, were examined; blood cultures were made in the cases of pneumonia; the sputums were injected into white mice, and finally, cultures were made at necropsy.

METHODS

1. In studying the secretions from nose and throat, the culture medium used was blood agar made by adding 5 per cent. human blood to meat infusion agar that was neutral or nearly so, in reaction, phenolphthalein being used as the indicator. Cultures were made by streaking blood agar plates with the cotton swabs that were used in taking the nose and throat cultures, further distribution of the streaks being effected with a platinum loop. Smears on glass slides were made at the same time and stained with Gram and Hiss capsule stains.

It may be noted that although it is now known that the best medium for the cultivation of the Pfeiffer bacillus is agar to which blood has been added while the agar was hot (about 90 C.), the reports so far issued are based on results obtained with the use of plain blood agar. Accordingly, it may be said that the results herein reported are perfectly comparable with the results of others.

In searching for colonies of Pfeiffer bacilli on blood agar plates, it was found that often two or three days were necessary for development of the colonies. At first, owing to the great amount of material to be examined, this time was allowed accidentally as a result of delay; later, all cultures were purposely kept for at least three days before being discarded.

---

*From the Walter Reed General Hospital.

[2] Strumpell, A.: München. med. Wchnschr. **37**: 90, 1890.
[3] Duflocq: Rev. de méd. p. 85, 1890.

2. The common method used in making blood cultures was by adding 5 c.c. of blood to each of two flasks of infusion broth; but in about twenty instances plates were poured also, in which 1 and 2 c.c. of blood and 12 c.c. of melted infusion agar were used.

3. Sputums were thus examined: Smears were made on slides and stained by gram and capsule stains. Washed portions were streaked on blood agar plates, and were injected intraperitoneally into white mice, and the latter, after death, were examined in the usual way for pneumococci and cultures of the exudate made on blood agar and smears of the exudate examined microscopically.

4. For examining specimens at necropsy, blood agar plates were used, except in the case of body fluids, which were put into plain broth, as well.

RESULTS

1. *Nose and Throat Smears and Cultures.*—This portion of the study was made entirely at Camp Lee, at a time when the epidemic was at its height and typical cases were daily entering the hospital in great numbers.

A. Smears: It was considered very important to examine direct smears from the nose and throat, since it seemed logical to expect to find the Pfeiffer bacillus in large numbers in these discharges if such were the cause of the disease. Forty-nine patients in one ward were studied. This number included about ten who had already developed pneumonia. The same swab that had been used in making cultures was rubbed on a glass slide. The smear was stained by Gram and capsule stains and an examination made to determine the character of bacteria present. Of these forty-nine cases, thirteen showed minute gram-negative bacilli which resembled the Pfeiffer bacillus.

B. Cultures: Of the forty-nine patients whose nasal and pharyngeal secretions were studied by direct smear, there were two who yielded cultures of Pfeiffer bacilli. Attempts to transplant these cultures to blood agar resulted in failure of growth. Besides these patients, seventy-four early cases were examined, sixteen of which were examined on admission to the hospital, and fifty-eight in regimental infirmaries. Of this group of seventy-four cases, three gave cultures of Pfeiffer bacilli.

Of 123 throat cultures, therefore, Pfeiffer bacilli were found five times. That this number is too small is indicated by the fact that minute gram-negative bacilli were found in direct smear in 26.5 per cent. of the forty-nine cases examined. There is no doubt that the use of blood agar plates is ineffective in detecting cultures of Pfeiffer bacilli in all cases in which they occur.

2. *Blood Cultures.*—Except in the few instances in which pneumococci were isolated, no positive cultures were obtained. This result is therefore of negative value. One hundred and thirty-six cultures were made in the manner described, with positive pneumococcus cultures in five instances.

3. *Sputum Examinations.*—Sputums were examined from sixty-five patients by the methods described above. Pfeiffer bacilli were seen in the smears of peritoneal exudate and obtained in cultures therefrom in eighteen instances, or 27.6 per cent. Other bacteria accompanied these. Of the pneumococci, Type I occurred five times; Type II, twice; Atypical II, six times; Type III, once, and Type IV, thirty-two times.

4. *Smears and Cultures of Necropsies.*—The results obtained at Camp Lee are considered separately from those at Camp Dix, because the course pursued was somewhat different. The same kind of culture medium was used at the two places, but at Camp Dix, the trachea was examined in all cases, and portions of the lungs were injected into white mice. As stated before, the situation at the two camps was different in that the necropsies at Camp Lee were performed on persons who had died in the beginning or middle of the epidemic, while at Camp Dix, the epidemic had passed, although there were many cases of pneumonia in the hospital, and the quarantine had not been abolished. Most of the necropsies were performed by Dr. MacCallum. His descriptions appear elsewhere.

A. Smears: Forty-four necropsies were studied at Camp Lee. Particular attention was paid to the examination of direct smears from the lungs in these cases, since this point was emphasized by Pfeiffer. However, the lungs did not present the features characterized by Pfeiffer as typical of infection by the Pfeiffer bacillus. In his cases, purulent bronchitis and purulent bronchopneumonia were the typical lesions, and smears of the pus from such sources revealed usually great numbers of tiny gram-negative bacilli in the leukocytes.

The most striking feature of the smears of lung tissue from the necropsies at Camp Lee was the small number of pus cells in the majority of instances, although in most of the cases the patients were ill at least a week. In most instances the smears showed great numbers of red blood cells and enormous numbers of pneumococci. The latter could easily be distinguished by their shapes and capsules. Furthermore, the bacteria seen in greatest number in the smear were correspondingly prominent in the cultures. In other words, the evidence revealed by the smear was an accurate index to the result of the culture. There were three cases in which Pfeiffer bacilli appeared in the smears and cultures. These cases differed from the others in having very few bacteria in the smears.

There were also nine cases in which hemolytic streptococci were present in the culture, in all but two of which very few bacteria appeared in the smears.

B. Cultures: Of the forty-four cases under consideration, three yielded cultures of the Pfeiffer bacillus; seven of hemolytic streptococci, alone; two of hemolytic streptococci with pneumococci; twenty-eight of Pneumococcus IV, alone; two of Pneumococcus IV with hemolytic streptococci; one of Pneumococcus I, and one of pneumococcus (untyped). Two cases yielded a number of kinds of bacteria the identity of which was not determined.

These cultures were taken from the lungs, heart blood, spleen and from the exudate from the pericardial and pleural cavities, if such exudation occurred. Besides the bacteria referred to, there were frequently colonies of staphylococci, gram-negative diplococci, probably of the *M. cartarrhalis* variety, and coarse colonies of small gram-negative bacilli resembling Friedländer bacilli.

The number of times that pneumococci occurred in smears and cultures, almost to the exclusion of other bacteria, left no doubt concerning the pathogenic activity of these organisms; but since they are very commonly present in the mouth, no association with the disease "influenza" was suggested.

CASES AT CAMP DIX

There were ten necropsies. In general, the number of kinds of bacteria was greater than at Camp Lee. Cultures were made from the trachea in all cases; from the bronchi in six, and from the accessory sinuses in two cases in which these cavities were involved; from the lungs in all cases; and portions of lung tissue were ground and injected intraperitoneally into white mice. Smears were made from all these sources. The cultures of the trachea were made by snipping small pieces of the mucosa and rubbing these on blood agar.

Three cases stood out from all the others. In these the smears from the trachea showed large numbers of pus cells, and large numbers of minute gram-negative bacilli. The bronchi and lungs displayed the appearances described by Pfeiffer. In the cultures from these cases the predominating organism was the Pfeiffer bacillus. In one case, no other bacteria appeared in the cultures from the bronchi and lungs; in the other two, staphylococci were also present. It was striking that all the mice inoculated with lung tissue in these cases survived. No other cases yielded Pfeiffer bacilli in the cultures of the lungs, although five others showed these bacilli in cultures from the trachea or bronchi. In three cases Pneumococcus IV occurred in the lungs and heart blood, and in two of these, in the pericardial fluid and abscess of the rectus muscle as well. Hemolytic streptococci occurred in the lungs in two cases, and in two cases there were mucoid colonies of small gram-negative bacilli which resembled Friedländer bacilli and which grew in company with Type IV pneumococci. One case gave a rich culture of *M. catarrhalis* together with untyped pneumococci, from the lungs. In one case, Pneumococcus III occurred in the lungs, heart blood, pleural and pericardial fluids.

These results do not lead to a definite conclusion regarding the cause of the disease. In the three cases in which Pfeiffer bacilli were present in large numbers, a new feature was added to the appearances of the bronci and lungs, namely, the large amount of purulent exudate in the bronchi and bronchioles. Since all the bacteria found in these cases—including the Pfeiffer bacillus—are present in normal throats in a fairly large number of cases, stronger evidence is needed before ascribing to any of them the causation of influenza.

COMMENT

These results suggest that influenza is a disease caused by some as yet undiscovered agent, which produces inflammation of the entire respiratory tract, and effects a very profound lowering of resistance, which is perhaps expressed by the constant and striking leukopenia. Lack of reaction is the most noticeable clinical feature. Under these circumstances, invasion follows by the various bacteria that are capable of becoming pathogenic, although harmless in the normal mouth.

The prominence that the Pfeiffer bacillus has enjoyed with regard to influenza makes it timely to discuss the status of this bacillus. In 1889 many investigators studied influenza. Clinical descriptions were accurate and complete; but it is difficult to find a clear description of the lungs, and bacteriologic methods were insufficient to detect the organism later described by Pfeiffer as the cause of the disease. But the features emphasized by Pfeiffer, namely, purulent bronchitis and bronchopneumonia, were not mentioned by the early writers as characteristic of the disease. Strumpell[2] refers to two forms of lesion in the lungs: a diffuse lobular catarrhal pneumonia almost always in the lower lobes; and diffuse purulent bronchopneumonia. The first type of lesion was present in the majority of cases. During the epidemic, various bacteria were found. Ribbert[4] found hemolytic streptococci most often; Marmorek[5] encountered pneumococci; in more searching studies, Weichselbaum[6] found pneumococci to be the most frequent invaders. Similar results were obtained by Kirchner[7] and Babes,[8] while Levi[9] found pneumococci with streptococci and staphylococci. The inference drawn by all these investigators was that influenza merely prepared the way for the secondary invasion by the bacteria that they described. Two years after the epidemic, Pfeiffer[10] studied a number of cases of purulent bronchitis and purulent bronchopneumonia that were called "influenza." In the bronchial secretion from these cases, he was able to observe and cultivate minute gram-negative bacilli that he had seen in the sputums from cases during the previous epidemic of influenza. Since he showed that they could not be cultivated by the methods used by the earlier workers, it was held as probable that these bacilli were the agents in the epidemic of 1889. He found that the bacilli would not grow on any medium without the addition of blood. His descriptions of the sputum and of the lungs are very definite. He characterized the sputum as being yellow-green, thick and sticky, and frequently very copious. In the lungs he found bronchopneumonic nodules, in the center of which the cut bronchiole yielded pus, identical with the material in the sputum, and composed of pus cells embedded in mucus in which great numbers of the bacilli could be found. He argued that these bacilli occurred only in the disease he was studying, and therefore he named it the influenza bacillus. Since then, all conditions in which the Pfeiffer bacillus has been found have been called "influenzal." Weichselbaum[11] studied five such cases of purulent bronchopneumonia and found the Pfeiffer bacillus in all cases. Grassberger[12] obtained similar results.

French investigators did not accept the results of Pfeiffer. They argued that since this bacillus was found in conditions other than influenza, it could not be the cause of this disease. This view is well presented by Rosenthal.[13] Indeed, many investigators began finding the Pfeiffer bacillus in a variety of diseases, obviously not associated with the epidemic. Wynekoop[14] described three cases of conjunctivitis that gave pure cultures of Pfeiffer bacilli. Süsswein[15] recovered this organism in ten out of twenty-one cases of measles. Leiner[16] studied eleven cases of diphtheria complicated by purulent bronchitis, and all gave cultures of the same bacillus. Auerbach[17] found the Pfeiffer bacillus

a common inhabitant of the tonsils and tracheal secretion in cases of diphtheria, scarlatina, measles and sore throat. Wollstein[18] studied a large number of cases of respiratory infections in infants, and found the Pfeiffer bacillus in sixteen out of fifty-three cases of bronchopneumonia; in eleven of forty-five cases of bronchitis; in eight of twenty-six cases of measles; in eight of twenty-four cases of tuberculosis, and in three of seven cases of empyema. The method used was to plant coughed-up mucus on blood agar plates. Davis[19] found Pfeiffer bacilli in sixty-one of sixty-eight cases of pertussis, and with great frequency in measles, chickenpox and bronchitis, as well as in two of twenty normal throats. In a very exhaustive clinical and bacteriologic study of 186 cases of respiratory infection, occurring between 1902 and 1904, Lord[20] found Pfeiffer bacilli in overwhelming numbers in 25 per cent. by cultural methods. In Camp McClellan last winter there occurred two cases of bronchopneumonia, presenting at necropsy appearances identical with those described by Pfeiffer, in which Pfeiffer bacilli were recovered from the lungs in almost pure culture; and at Fort Sam Houston in February and March, 1918, during the epidemic of streptococcus pneumonia following measles, these bacilli were present with considerable frequency, though they were disregarded as an etiologic factor in the pneumonia under study.

The foregoing indicates that the Pfeiffer bacillus is at certain times, at least, definitely pathogenic. It is associated, most typically, with purulent inflammation of the bronchi and bronchioles. Its appearance in such a variety of conditions primarily caused by other agents robs it of that individuality which it should possess to be the producer of such unique epidemics. If it can be shown in the future that this bacillus occurs with frequency in normal throats, then it can no longer be suspected of even being related to the cause of influenza. In this regard, the report of the pneumonia commission[21] at Camp Pike, written long before influenza appeared in this country, is of value. Sputums from 132 normal individuals were studied by injecting the sputums into white mice. Pfeiffer bacilli were recovered in about 35 per cent. of the cases.

On the other hand, if these bacilli are merely secondary invaders, the frequency with which they occur in the cases of influenza reported by others suggests that these bacteria are very common in normal throats. But the evidence at hand seems insufficient to warrant the statement that the Pfeiffer bacillus is the cause of influenza.

Two points must be settled: First, the question of identifying and classifying these bacilli must be investigated; and second, the exact frequency of their occurrence in normal throats must be ascertained.

CONCLUSIONS

1. Epidemic influenza is a disease of unknown origin.
2. Various bacteria, commonly found in normal throats, are encountered in the cultures from influenza patients.
3. The experience of many investigators indicates that the Pfeiffer bacillus may be pathogenic and cause a form of purulent bronchitis and bronchopneumonia.
4. The Pfeiffer bacillus occurs with striking frequency in the throats of patients with measles, pertussis, diphtheria and scarlatina, especially when these conditions are complicated by the form of bronchitis or bronchopneumonia mentioned.
5. The Pfeiffer bacillus occurs with frequency in normal throats, in times when no epidemic of influenza exists.

PATHOLOGY OF THE PNEUMONIA FOLLOWING INFLUENZA

W. G. MacCALLUM, M.D.
Contract Surgeon, U. S. Army
BALTIMORE

Contributions to the study of the pneumonia following influenza in the recent epidemic are still desirable because of the difference of opinion as to its nature and causes that has been evidenced by numerous published papers. All have agreed as to the uniform character of the disease influenza wherever it has appeared in its swing across the continent, but conflicting views have been presented as to its etiology and as to the relation of various bacteria discovered in the respiratory tract, especially in cases of pneumonia, to the original disease and to the pneumonia. The dispute is concerned more particularly with the part played by the *Bacillus influenzae* of Pfeiffer, which some authors have found so regularly present as to lead them to consider it the cause not only of the pneumonia but also of the original epidemic disease influenza. Indeed, it was launched by Pfeiffer as the cause of influenza. Investigators in other localities have failed to find this organism, and this has been explained by those more successful as being the result of technical incompetence.

The present study was made by a commission consisting of Major R. A. Kinsella and myself, sent by the Surgeon-General of the United States Army, first to Camp Lee in Virginia and later to Camp Dix in New Jersey. Twenty necropsies were performed at Camp Lee when the epidemic was nearing its height, and twelve at Camp Dix at a time when the influenza was practically over but many cases of pneumonia were still in the hospital. Between these visits and afterward, seventeen necropsies were performed at the Johns Hopkins Hospital on patients who died there in the early part of the epidemic of influenza.

It has been stated that the influenza bacillus may be present in the upper respiratory tract, larynx and bronchi when it is not to be obtained from the substance of the lung. On this account, cultures and smears are made from bronchial pus, from the mucosa of the trachea, larynx, etc. This precaution was not observed in the Camp Lee cases, although cultures were made from the accessory nasal sinuses whenever possible; but it was carried out at Camp Dix and later at the Johns Hopkins Hospital. It was suggested that this might account for our inability to find the influenza bacillus in all the cases at Camp Lee; but the later study of these cases has proved this to be unfounded. A combination of Goodpasture's and Weigert's stain[1] permits a very satisfactory survey of gram-negative and gram-positive bacteria in the tissues. The organisms are brilliantly stained, the gram-negative red, the gram-positive blue, black or purple, so that it is easy to recognize the presence of influenza bacilli even when a few are mixed with great numbers of gram-positive bacteria. This stain showed that influenza bacilli, when they occurred in the bronchi at all, penetrate into the smaller bronchioles and could hardly be missed in a culture taken from the lung unless the medium employed for the culture was unsuited to their growth. The morphology of the influenza bacillus when clearly seen in the tissues or in smears is very characteristic, and their discovery in this way was nearly always confirmed by reference to the records of the cultures. Indeed, the morphologic recognition of the predominant organisms in the tissues seemed surprisingly accurate when compared later with the results of the cultures.

---

[1] MacCallum, W. G.: A Stain for Influenza Bacilli in Tissues, J. A. M. A. **72**: 193 (Jan. 18) 1919.

The accompanying table gives the predominant organism in each case, as decided by consideration of smears, cultures and sections usually with the aid of mouse inoculations. The influenza bacillus is recorded in the table whenever found even in small numbers or in the trachea or nasal sinuses alone. When it was the predominant organism it is put first.

Some doubt may be admitted as to the nature of these bacilli in certain cases, and Colonel Nichols has pointed out the occurrence of members of the Friedländer group. In Cases 85 and 87 it was thought that the bacilli resembled the Friedländer bacillus in culture.

From the table it is seen that at Camp Lee most of the cases showed Pneumococcus Type IV without any influenza bacilli. This conclusion is not reached from the mere failure of cultures but from the examination of smears from the lung and stained sections from lung, bronchi and trachea, often including also the larynx and nasal sinuses. No considerable number of influenza bacilli could be overlooked, and it has been observed repeatedly that they are not made to disappear by even an overwhelming growth of other bacteria. They were definitely found in three cases, and there were in three other cases a few gram-negative bacilli which might be thought to be influenza bacilli. At the Johns Hopkins Hospital similar methods revealed no influenza bacilli whatever. At Camp Dix, on the contrary, influenza bacilli were found in every case.

From these results it seems necessary to draw one of two conclusions: In certain regions or in certain communities the influenza bacillus may be so prevalent as a relatively harmless inhabitant of the throat that when some epidemic disease, such as influenza, lowers the resistance of many persons, it becomes the natural secondary invader capable of producing pneumonia. This might be regarded as the endemic occurrence of a potential cause of pneumonia.

On the other hand, it has been shown that a single carrier of the hemolytic streptococcus, when introduced into a hospital ward full of patients with measles, may be the source of an epidemic of streptococcus pneumonia. It seems quite probable that secondary infection with the influenza bacillus with the production of pneumonia may in the same way have a local epidemic character.

No satisfactory evidence has been brought forward to show that the epidemic disease influenza is a bacterial infection. It is evidently a general or systemic infection not especially affecting the respiratory tract and analogous in many respects, as Bloomfield has pointed out, to the well known acute exanthematic diseases. It produces an extreme depression of the general resistance of the individual to the invasion of bacteria, as is shown in one respect by the characteristic leukopenia, which may persist in spite of the development of pneumonia. Under these circumstances, bacteria that are present in the throat or are introduced from without readily invade the tissues of the whole respiratory tract and give rise to pneumonia. Because of the lack of resistance, they multiply until they are present in such enormous numbers as are never seen under ordinary conditions. This must be regarded as a secondary infection. The secondary infection apparently determines the anatomic type of the pneumonia, but there may be other successive infections with different organisms, so that it often becomes difficult to say which is the secondary and which the tertiary or quaternary infection. It seems possible that one or more of these organisms may be present without producing any recognizable lesion, while a later invader causes pneumonia, or that when one organism has produced its characteristic pneumonia, others may grow beside it without altering the lesion. On the other hand, a final invader may completely mask the original pneumonia by producing a widespread necrosis.

The influence of the predisposing disease, influenza, is such as to permit the extremely rapid growth of the organisms and minimize the reaction of the tissues. Any attempt to recognize the nature of the infecting organisms on the basis of our knowledge of the specific anatomic effects that they produce in ordinary times must be made with this in view.

It is perhaps questionable whether we have as yet enough carefully studied cases of pneumonia produced by unmixed infections with each of the bacteria concerned, on the basis of predisposing influenza, to allow us to decide as to the precise anatomic effect that is characteristic of each. Thus it is probably impossible to distinguish a Type I pneumococcus pneumonia from one produced by pneumococcus Type II. It is difficult to say whether *Staphylococcus aureus* produces, under these circumstances, a pneumonia that is distinct from these, although many cases have been studied and it is possible that some criterion will be found that will aid in making this distinction. Those produced by the hemolytic streptococcus are probably recognizable as such, and it appears that when alone or as the predominant organism the influenza bacillus of Pfeiffer produces an interstitial bronchopneumonia that is definitely and easily distinguished from all the others. The difficulty in making these distinctions may be due in part to the fact that mixed infections are the rule.

At the Johns Hopkins Hospital and at Camp Lee we observed patients in an early stage of the epidemic, evidently those of great susceptibility, who succumbed quickly to pneumonia. At Camp Dix the epidemic that had raged with high mortality was practically over, and deaths were occurring among those who had survived somewhat longer and were beginning to present evidences of late extensions of the secondary infection in the form of pleurisy with effusion, endocarditis, scattered infarcts, etc. It seems that the performance of a series of necropsies in one place throughout the whole course of an epidemic might result in this way in revealing all the successive stages of the disease.

TYPES OF PNEUMONIA

In persons who have just passed through an attack of influenza, the following types of pneumonia may be recognized, although it is evident that the distinctions may be rendered indefinite by simultaneous infection with other organisms: Pneumonia caused by (1) the pneumococcus; (2) the staphylococcus; (3) the streptococcus, and (4) *B. influenzae* of Pfeiffer.

1. *Pneumococcal Pneumonia.*—When the pneumococcus occurs in pure culture, and also in those cases in which it is the predominant organism even in the presence of influenza bacilli and other organisms, a characteristic form of pneumonia is produced under the conditions of lowered resistance. In most instances there is very little fluid in the pleural cavity, and the surface, instead of being covered with a shaggy exudate of fibrin, is only slightly dulled. There are brick-red, paintlike patches here and there, and sometimes small, elevated, grayish yellow flecks which become confluent in patches. The pleura and interlobular septums and remaining framework of the lung appear to be unchanged. The bronchi are not especially conspicuous. Their walls are not thickened, and while they may sometimes contain in the later stages fibrinous molds, they are usually empty or partly filled with a thin, brownish or blood-stained, frothy fluid. Their mucosa shows no marked alteration from normal. The blood vessels are normal.

On external inspection of the lung, it is frequently possible to recognize sharply outlined consolidated lobules alternating with air-containing and atelectatic lobules. The lobular character of the consolidation is in these cases well marked, although it tends to lose its definiteness through the confluence of adjacent areas. No general statement can be made as to the location of the consolidation, but it usually affects the posterior and lower part of each lobe, and the posterior part of the lower lobe is especially frequently involved.

The cut surface of the lung shows in the more acute cases a peculiar lobular or confluent consolidation which corresponds well with what is commonly written of the stage of engorgement in the description of lobar pneumonia. Bronchioles, blood vessels and the framework of the lung are not appreciably altered. The substance of the lung is firm, elastic, and not rigid as in later stages; but it pits on pressure, exuding a great quantity of blood or brownish blood-stained fluid. The surface is smooth, moist, slightly elevated above the surrounding tissue, grayish red or brownish red, and coarsely spongy. Distinct but minute depressions can be seen everywhere, filled with a translucent, gelatinous, red fluid. These are too large to be the cavities of alveoli, and are separated by what appear to be thick walls of homogeneous tissue. They are in fact the widened ductuli alveolares filled with fluid and separated by areas of alveoli filled with a somewhat firmer exudate. No visible or palpable plugs of exudate project from any part of the surface, and there is nothing of the roughness that this produces in later stages. Nevertheless, the consolidated tissue is easily distinguished from that surrounding it, because it has lost the satiny texture of the normal lung, which may be pulled this way and that, like silk gauze. In the area of pneumonia, despite its smoothness and moist, rather translucent surface, the distended form of the meshes is maintained.

Microscopically these areas show an extraordinary dilatation of the ductuli alveolares, which are filled with clear fluid containing only a few leukocytes and a delicate coagulum. They are lined with a curious hyaline substance which begins in a layer overlying the cylindric epithelium in the terminal part of the bronchiole and often runs over the orifices of the atriums or enters them and extends toward the air sacs. It does not give the reactions of fibrin. The alveoli contain an exudate of fluid with a few leukocytes and mononuclear cells, often overshadowed by great numbers of well preserved red corpuscles. These cells are held together by the most delicate, filmy network of fibrin. Great numbers of pneumococci are scattered throughout the exudate. The alveolar walls maintain their normal appearance.

Later stages in the pneumonia show within these areas patches of rough, gray, consolidated tissue, from which definite plugs of exudate project. Every transitional stage may be found, up to the most advanced lobar consolidation, with dense gray hepatization.

2. *Staphylococcal Pneumonia.*—We encountered no cases in which the staphylococcus was present alone and, indeed, none in which it occurred in very great numbers. No definite statement may be ventured as yet, therefore, regarding the type of pneumonia produced. In one case in which the staphylococcus appeared to be the predominant organism, the lesion was indistinguishable from that just described for the pneumococcus.

3. *Streptococcal Pneumonia.*—When *Streptococcus hemolyticus* occurs alone in these cases, as in Cases 219 and 5720, the lesion produced is practically identical with that described as "lobular pneumonia" in certain cases of the previous epidemic. There is not necessarily extensive pleural effusion, but the pleura may contain a small amount of blood-stained fluid. The interlobular septums are edematous, and the bronchial walls are slightly thickened. The area of consolidation is indefinitely outlined, and in places it is deep red or almost black, evidently as the result of laking of blood.

Microscopically the bronchi and alveoli are packed with leukocytes, blood and fibrin, and loaded with tangled masses of streptococci. Much of the blood is laked and appears in the form of shadows. Much of it, again, is coalescent into a beaded network of pink-staining, hyaline material. The capillaries in the alveolar walls are plugged in many places with hyaline fibrinous thrombi, and a similar hyaline material is found in the walls of the larger blood vessels. The bronchial walls are infiltrated with leukocytes, and the epithelium is lifted up or destroyed. Whole areas of the lung, although retaining their form, are entirely necrotic, the alveolar cavities being packed with almost solid masses of streptococci. Lymphatics are everywhere distended with exudate containing enormous numbers of streptococci. In none of these cases was there enough resistance to give time for the development of an interstitial bronchopneumonia.

4. *Pneumonia Produced by Bacillus Influenzae of Pfeiffer.*—In two cases at Camp Dix the influenza bacillus was present in pure culture, and in others it was the predominant organism. Tissues from another case in which the influenza bacillus occurred alone were sent me from Camp Jackson. It is easy to recognize the type of pneumonia produced by this organism, since it is fundamentally different from the others.

There is no abundant pleural exudate, although the pleural surface may be covered with fibrin or with old adhesions. The bronchi exude a thick, yellow pus, and the bronchial glands are moderately enlarged.

On section, the lung is found to be in large part air-containing, but it is studded throughout with palpable shotlike nodules or with somewhat larger patches of firm consistency. The cut surface of these nodules is smooth, and they are grayish yellow. They are seen to be peribronchial, so that when they stand alone the center is occupied by the lumen of a bronchiole. The remaining lung substance is air-containing or indurated and grayish.

Microscopically it is found that the bronchi are filled with an exudate of leukocytes, among which numerous influenza bacilli are lying, sometimes in clumps and scattered freely, but most often enclosed in phagocytic cells. The wall of the bronchus is greatly thickened by infiltration of mononuclear cells with a few leukocytes, and by the new formation of connective tissue cells. The alveolar walls for a considerable distance about this are similarly thickened, infiltrated and indurated. The alveoli contain an exudate which is usually rich in leukocytes, but which is often predominantly composed of desquamated epithelial cells and dense fibrin. In this exudate it is rarely possible to find influenza bacilli. Organization is advancing rapidly, and in many instances it has completely replaced the fibrinous exudate with fibrous tissue over which epithelial cells have grown.

The lymphatic channels in the bronchial walls and the widened interlobular septums are inconspicuous, and none are found distended with exudate. There is no intense infection of the pleura or great outpouring of exudate. These two facts, together with the relatively inconspicuous part played by the polymorphonuclear leukocytes in the alveolar exudate, and in the exudate infiltrating the walls of the bronchi and alveoli, are all that distinguish this pulmonary change from the interstitial bronchopneumonia caused by the hemolytic streptococcus, as described in previous papers. The sharp contrast between this form and those produced by the pneumococcus and streptococcus is very evident.

In describing the forms of pneumonia caused by the hemolytic streptococcus, it was shown that interstitial bronchopneumonia was produced when the organisms encountered a high resistance, through which the tissues succeeded in barricading themselves against invasion and repressing the multiplication of the bacteria, but that with a lapse in the powers of resistance there might be produced in the same case areas of lobular pneumonia in which an exudate of leukocytes filled the alveoli. In this exudate the streptococci multiplied with great rapidity.

In the case of the influenza bacillus an exactly analogous condition exists. There are cases in which an interstitial bronchopneumonia has developed, with restriction of the bacilli to the bronchial exudate, but in which later, probably with lowering of resistance, other lesions presenting the character of lobular pneumonia have arisen in which the more distant alveoli are packed with leukocytes with abundant influenza bacilli.

In the doubt that for a time assailed me as to whether the interstitial form of bronchopneumonia seen in Texas might after all be due to the influenza bacillus rather than to the predominant streptococcus, I have been much reassured by this finding. Although influenza bacilli were found as accompanying organisms in a few of those cases, there were many in which the typical lesions were produced by the streptococci alone. But now that it appears that streptococci and influenza bacilli may in precisely similar ways be governed, as regards the character of the lesions they produce, by the resistance opposed to them, it seems unnecessary to ascribe one type of lesion to the streptococcus and another to the influenza bacillus.

Various complications that occurred in these cases of pneumonia will be discussed in detail in another paper. They include such things as hyaline degeneration of the rectus abdominis muscles, ulcerative laryngitis and tracheitis, and generalized emphysema.

CONCLUSIONS

1. The epidemic disease influenza resembles in many respects measles and other acute exanthematic diseases. Nothing is definitely known as to its causative agent.

2. It produces great lowering of resistance to bacterial invasion and is therefore often followed by pneumonia caused by the different types of pneumococcus, *Staphylococcus aureus, Streptococcus hemolyticus* or the influenza bacillus of Pfeiffer.

3. In some regions the influenza bacillus is a particularly common secondary invader. In other regions it is insignificant, its place being taken by one of the pneumococci. This may depend on an endemic or epidemic distribution of these organisms as inhabitants of the nasopharynx.

4. The form of pneumonia produced after influenza is greatly modified by the lowering of resistance, which allows huge numbers of bacteria to grow. Nevertheless the types caused by the pneumococcus, streptococcus, and influenza bacillus are to be sharply distinguished. Probably the type caused by the staphylococcus will be shown to have distinctive peculiarities when adequate material has been studied.

Exemia in Shock.—In shocked men there is a concentration of the blood in the capillaries, indicated by a marked difference between the capillary and the venous blood counts. This difference may amount to as much as 2,500,000 corpuscles per cubic millimeter in favor of the capillary count. The evidence from blood counting indicates that the "lost blood" of shock (the exemia) is to a considerable degree to be found in the capillary bed.—*Review of War Surgery and Medicine.*

THE MIGRATORY APPENDIX

J. E. ALLABEN, M.D.
Attending Surgeon, St. Anthony Hospital
ROCKFORD, ILL.

There are certain types of tumors in the abdomen, usually cystic in character, that become attached by adhesions at a point distant from their origin and finally become detached entirely from their original locality, their nutrition being maintained through blood vessels in the new adhesions. These tumors are known as migratory tumors. The peculiarity of these growths suggested to my mind the caption of this article. It is not difficult to understand that the appendix might be subjected to a similar condition, and, being separated from the cecum, might maintain an entirely separate life through new blood vessels formed in abundant adhesions. A condition of this kind is well illustrated by the following case:

REPORT OF CASE

Miss F. M., aged 23, had suffered from a gonorrheal infection for which I had treated her for nine months. In August, 1917, she had recovered sufficiently so that treatments were discontinued. She reappeared in August, 1918, complaining of pain in the right iliac region. This pain became so acute that she was confined to bed. There was some nausea, elevation of temperature and increase of pulse rate. The patient complained of tenderness in the right iliac region on pressure. There was much difficulty in getting a bowel movement. On account of the previous history of tubal disease it was a question whether the trouble was pyosalpinx or appendicitis. I decided to make an exploratory examination, which I did.

I operated on her, Sept. 10, 1918, at Rockford City Hospital. The incision was made through the right rectus muscle, so that it might be enlarged in either direction to make free access to the appendix or tube as might be necessary. On opening the abdomen I found a considerable mass of omentum adherent in the right iliac fossa. This I ligated *en masse* and removed it entirely. The intestines in this region were kinked and firmly adherent to each other, thus accounting for the partial intestinal obstruction. The intestines were covered with a yellow plastic exudate. Sterilized gauze was used in separating the adhesions. The search was made at the cecum for the appendix, but I was unable to locate it. The right fallopian tube was distorted and adherent. Pressure on the tube forced a few drops of pus out of the fimbriated extremely. The tube was ligated and removed. At this stage of the operation the distal end of the appendix was observed protruding about half an inch through a mass of adhesion in the right iliac fossa. The appendix was dissected out from these adhesions as thoroughly as possible. The toilet of the peritoneum was finished by pouring about 4 ounces of ether into the pelvis and right iliac fossa, so that any infection of this locality through the tube might be counteracted and the peritoneum closed in layers.

No doubt a continual leakage of pus from the right tube produced the intestinal adhesions, and the appendix, which had become entirely separated from the cecum, was kept alive through new blood vessels formed in the many adhesions about this organ.

The patient made a good recovery without complications, save a slight infection in one of the skin stitches.

COMMENT

It is difficult to tell whether the appendix or the tube was primarily the offending organ in this case. It is interesting to speculate as to what pathologic condition would have followed if such an appendix had been left entirely to nature. It is my own opinion that the appendix and the adhesions would ultimately have been absorbed without causing any trouble, but it is plainly to be seen that a tube with a patulous extremity periodically leaking pus into the peritoneum might have caused serious complications. This condition of the appendix may account for some of the cases reported in which no appendix was found.

BRONCHOPNEUMONIA DUE TO HEMOLYTIC STREPTOCOCCI FOLLOWING INFLUENZA *

ERNEST W. GOODPASTURE, M.D. (Boston)
Lieutenant (Junior Grade), M. C., U. S. N. R. F.
CHELSEA, MASS.

The bacteriology and pathology of bronchopneumonia during the last two months (December and January) have become quite different, at the Chelsea Naval Hospital, from that found during the preceding three months, including the most severe period of the first local outbreak of influenza. In the earlier period, cultures of Pfeiffer's bacillus were obtained from the lungs in 86 per cent. of cases postmortem, the organism often being found in pure culture, pneumococci in 50 per cent., and hemolytic streptococci in 13 per cent.; while during the last two months, cultures of hemolytic streptococci have been obtained from the lungs in 100 per cent. of those examined at necropsy, and in the majority of instances pure cultures were obtained. Pfeiffer's bacillus was demonstrated in only two cases of a total of sixteen, and these two were examined the first week of December.

This marked variation in the type of invading organism in bronchopneumonia is of particular interest since it represents the experience of a single station during a relatively short period of time; and we are now familiar with wide differences in bacteriologic observations from various sections of the country since the epidemic of influenza began.

From the twenty-six cases studied during the height of the epidemic in the early fall, we became more or less familiar with a type of pneumonia which was fairly typical of that series, and were able to recognize many modifications obviously due to secondary invasion by pathogenic organisms. An acute bronchiolitis characterized by the presence within the bronchioles of a dry exudate consisting of a few leukocytes, polymorphonuclear and mononuclear, mucus and fibrin, usually with partial or complete necrosis of the mucous membrane, and the presence of a characteristic irregular hyaline membrane on the infundibular and alveolar walls, were regarded as typical early lesions. Bronchopneumonia following this was fulminating in type and consisted in a widespread toxic injury to alveolar tissues, so that they became filled with fluid exudate, fibrin, and hemorrhage with extensive injury to alveolar walls and capillaries. From a study of these cases we stated that "the pulmonary injury and reaction being so acute and often widespread, and the fact that in certain very early cases bacteria of any kind are so scarce or not found at all, make us feel, notwithstanding the demonstration of influenza bacilli in pure culture in the lungs in all but one instance, that at this stage organisms are as yet comparatively few within alveoli, and their primary injury is due to a very potent toxic substance elaborated in and disseminated through larger air passages." Following this initial injury, pathogenic bacteria readily invaded the pulmonary tissue, producing injury and reaction more or less typical for the organism concerned. In striking contrast to the group of cases that constitutes the material for the present report, hemolytic streptococci at that time played a relatively small rôle as a secondary invader, complicating only five, or 13 per cent., of the cases. In three of these, multiple abscesses were present in the lungs, and in the other two streptococci and influenza bacilli were associated in the production of widespread bronchiectatic abscesses and ulcerative bronchitis.

---

* From the U. S. Naval Hospital.

The present report is based on the postmortem examination of sixteen cases, constituting all the cases of bronchopneumonia examined at necropsy during the past two months. Eleven of the patients developed empyema, and the pleural exudate yielded pure cultures of hemolytic streptococci.

CASES OF BRONCHOPNEUMONIA WITH PATHOLOGIC DIAGNOSIS

Case No.	Range of Leukocyte Counts	Pathologic Diagnosis	Bacteriology of Lungs	Clinical Diagnosis on Admission
1	6,600-12,800	Bronchopneumonia; no empyema	Influenza bacilli; hemolytic streptococci; pneumococcus Type IV	Influenza
2	15,000-13,000	Bronchopneumonia; empyema (bilateral)	Hemolytic streptococci; nonhemolytic streptococci; influenza bacilli	Influenza; bronchopneumonia
3	3,200	Bronchopneumonia; no empyema	Hemolytic streptococci	Influenza
4	13,000-48,000	Empyema (bilateral); pericarditis; slight pneumonia	Hemolytic streptococci	Bronchopneumonia
5	25,000	Bronchopneumonia; peritonitis; empyema	Hemolytic streptococci	Bronchopneumonia
6	12,000	Bronchopneumonia; empyema (bilateral)	Hemolytic streptococci	Bronchopneumonia; empyema
7	4,700-3,400	Bronchopneumonia; empyema (bilateral)	Hemolytic streptococci	Influenza
8	6,000	Bronchopneumonia; empyema (left)	Hemolytic streptococci	Influenza; bronchopneumonia
9	4,000-15,000	Bronchopneumonia; empyema (bilateral); peritonitis	Hemolytic streptococci	Influenza
10	8,000-10,200	Bronchopneumonia; empyema (bilateral)	Hemolytic streptococci	Empyema; bronchopneumonia
11	7,000	Bronchopneumonia; empyema (left)	Hemolytic streptococci	Influenza
12	16,800	Bronchopneumonia; empyema (left)	Hemolytic streptococci	Empyema; bronchopneumonia
13	5,000-8,200	Bronchopneumonia; no empyema	Hemolytic streptococci	Influenza
14	9,000-19,200	Bronchopneumonia	Hemolytic streptococci	Influenza
15	3,000-6,000	Bronchopneumonia	Hemolytic streptococci	Influenza
16	5,000	Bronchopneumonia	Hemolytic streptococci	Influenza

The accompanying table presents these cases. Although some of the patients entered the hospital with well-developed bronchopneumonia, in several instances the clinical diagnosis of influenza or post-influenzal pneumonia was made.

In five cases the empyema was bilateral, in four on the left, and once on the right side. In each instance bronchopneumonia was bilateral. One case showed an extensive streptococcal pneumonia in each lung with no pleural exudate, and is of interest because numerous fibrous adhesions were present over the lungs, suggesting the possibility of an increased resistance to the infection because of previous inflammation.

The lungs were moist and congested, often atelectatic where pleural exudate was voluminous. The areas of consolidation were grayish purple, and cut surfaces exuded a fairly thick, purplish pus. In the early stages of pleural inflammation the exudate is serous, containing relatively few cells and organisms; later it becomes thick pus containing enormous numbers of streptococci. In four cases the infection was very prominent in the lymphatics and interlobular tissue of the lungs. The lobules in areas of considerable size were found outlined by wide (from 3 to 4 mm.) yellow bands. These bands followed the veins and bronchi to the hilum. The lymphatics of the pleura may also be filled with streptococci. Abscesses have occasionally been found. Microscopically the alveoli are filled with polymorphonuclear leukocytes and usually enormous numbers of streptococci, with little or no fibrin. Often there is widespread necrosis. In no instance have we observed the appearances of interstitial bronchopneumonia, described by MacCallum, which occurs so frequently as a sequel to measles. The distribution of the pneumonia is usually lobular and rather massive. In cases of short duration it may be lobar in distribution and involve the greater part of the lung tissue. Nor have we recognized the toxic lesions of early influenzal pneumonia as seen during the first weeks of the epidemic, and I regard all the cases in this report as instances of primary streptococcus pneumonia frequently following an attack of influenza.

The question naturally arises whether some of these cases were not primarily streptococcus infections without influenza. Eleven of the sixteen had attacks typical of influenza which terminated in pneumonia; the diagnoses of the other five were questionable as to an attack of influenza. In view of the experiences last year at various stations of epidemic streptococcal infections of the respiratory tract, it does not seem unlikely that similar outbreaks will occur or are occurring this winter, and with the impressions of influenza so recently in mind there will probably be considerable confusion of the two diseases, especially as there do not appear to be any very certain criteria which distinguish them, particularly when bronchopneumonia is present. Symptoms of onset, leukocyte count and the fever chart may be quite similar, although apparently there is usually more complaint of sore throat with streptococcal infections.

At this hospital, during the period covered by the present report, hemolytic streptococci have been exceedingly prevalent in various forms of inflammation, and this unusual prevalence explains in part their high incidence as a cause of bronchopneumonia attacking persons whose resistance is lowered by influenza.

The absence of the pathologic evidences of a preceding or accompanying toxic inflammation of the lungs, which in the early part of the epidemic of influenza appeared fairly characteristic of the pulmonary lesions of this disease per se, makes me regard the cases of the present series as examples of primary streptococcal pneumonia.

Bronchopneumonia following influenza has at present absolutely no etiologic or pathologic definition, for the type of organism concerned and the type of lesion in the lungs are decidedly variable at different times even at the same station. It is essential to bear this fact in mind in any consideration of the pneumonic complications of influenza, especially from the standpoint of prospective treatment.

APPENDICITIS AT CAMP LOGAN AS A SEQUEL TO INFLUENZA AND PNEUMONIA

J. N. HALL, M.D.
Major, M. C., U. S. Army; Chief of Medical Service, Base Hospital
AND
FREDERICK G. DYAS, M.D.
Major, M. C., U. S. Army; Chief of Surgical Service, Base Hospital
CAMP LOGAN, HOUSTON, TEXAS

It is well known that the occurrence of several cases of acute appendicitis in rapid succession in a small community, typically in a boarding school or similar institution, is commonly in association with an epidemic affecting the respiratory tract. Most commonly we find streptococcic sore throat as the precedent disease, but not infrequently an epidemic of severe colds. Several such outbreaks have come under our observation. The studies of Rosenow are of special interest in this connection.

The increased number of cases of acute appendicitis requiring operation at Camp Logan since the recent respiratory epidemic has therefore attracted our attention. It is only fair to say at the start that the management of the medical service has been in the same hands since the opening of the hospital. The two chiefs of surgery, Major J. H. Blackburn and Major F. G. Dyas, have worked in closest cooperation with the chief of medicine, always under the general and close supervision of the commanding officer, Lieut.-Col. J. M. Willis, M. C. Thus absolute assurance may be given that the type of case recommended for operation has not varied during the entire period.

As showing the character of the epidemic, we may state that the admissions for influenza from Sept. 13 to Dec. 1, 1918, when it had ceased, numbered 4,126, and for pneumonia and bronchopneumonia 531 and thirty-six, respectively.

A careful estimate of the average number of men in camp from Sept. 15, 1917, the date of opening of the hospital, until Sept. 13, 1918, the date of the influenza outbreak, is 24,000, although the maximum number had reached 36,600. If we compute the average incidence of acute appendicitis requiring operation for the year, from Sept. 15, 1917, to Sept. 13, 1918, we find it to be 10.4 per thousand per year. The total number of cases in which operation was performed was 250, as given us by Lieut. F. H. Crail of the department of surgery.

During the period from Sept. 13, 1918, to Dec. 31, 1918, ninety-two patients were operated on, the average incidence per thousand per year being 30.66. The great reduction in the number of troops in camp meanwhile should be noted, the average being only 10,000 men. From September 13 to September 30 there were fifteen cases; in October, three cases; in November, thirty-nine cases, and in December, thirty-five cases. The falling off in October is wholly inexplicable, as the epidemic was at its height. The seventy-four cases for November and December would present a rate of 44.4 per thousand per year. No case demanded operation during the first seven days of January, 1919, and only two in the first twelve days. It is to be observed that the great number of operations came after the epidemic had passed the high point late in October, and the December quota, thirty-five cases, came after the epidemic had disappeared. We have collated the number of cases coming to operation with reference to previous attacks of appendicitis and to the occurrence of either influenza or pneumonia.

In the ninety-two cases, twenty-five patients had had previous well defined attacks of appendicitis; twenty had had influenza during the present epidemic, and four had had pneumonia. We might well consider the latter under the influenza heading, as presumably every patient with pneumonia in this epidemic had influenza first; five had had a "bad cold" during the epidemic—presumably mild influenza. Thus twenty-nine of the ninety-two patients had had influenza, pneumonia or a notably bad cold since Sept. 13, 1918. This number would not at all account for the great increase in the number of cases of operative appendicitis, and they constitute almost a trivial percentage of the total number affected by the epidemic.

An interesting feature of the respiratory epidemic was the great number of cases admitted to the hospital with the diagnosis of acute appendicitis in which, after a few hours' observation, we changed the diagnosis to either influenza or pneumonia, and in which the further course confirmed our opinion that no notable disease existed in the abdomen. In the influenza cases we assume that the symptoms leading to a diagnosis of appendicitis arose from the participation in the acute infectious process of the lymphoid tissues of the appendix, as is often noted in tonsillitis, measles and similar acute diseases.

In pneumonia the pain and rigidity were, at times, apparently of the same type, but were frequently due to the reflection into the abdomen of the pain of the diaphragmatic pleural involvement accompanying a pneumonia of the right lower lobe. It should be definitely understood that no such cases were even seriously considered for operation, although about fifty patients were received whose provisional diagnosis was wrongly given as appendicitis.

Of the ninety-two patients operated on the diagnosis of the pathologist was acute catarrhal appendicitis in fifty-four cases; acute suppurative appendicitis in fifteen and chronic catarrhal appendicitis with subacute exacerbation in twenty-three cases. The chief of surgery, Major F. G. Dyas, was the operator in twenty-nine of the cases; Lieut. F. H. Crail in fourteen; Capt. Arthur Love in twelve; Capt. E. R. Dumke in eleven, and others in a few scattered cases.

The findings that led us to recommend operation were identical with those on which we have depended in civil life in the absence of epidemic disease. There were generally noted abdominal pain, vomiting, moderate elevation of temperature and pulse rate, tenderness and rigidity in the lower right quadrant, and an increase in the white count, commonly with a relative polymorphonuclear increase. The blood findings were of more than usual value in view of the normal leukopenia of influenza. Due weight was, of course, given to the history of previous attacks.

Every case was examined with special care as to the presence of pneumonia or other acute respiratory disease, and the routine examination of urine was made. In no case in which we operated did we fail to find a pathologic justification for the operation according to the best judgment of the pathologist, the surgeon and the representative of the medical department. We have several times observed in former years, as many physicians have reported, a full fledged acute lobar pneumonia, generally in the right lower lobe, in cases in which we were told that the appendix removed the day before had been practically normal. We had no such occurrence in this series. It is necessary to mention this specifically, since the possibility of such error would almost certainly occur to many clinicians. No patient with acute respiratory symptoms was subjected to operation even though there might be present tenderness and rigidity in the abdomen, without several days of observation, and only three cases were sent to the operating room until after the subsidence of all such symptoms.

Our laboratory report is incomplete, since, during the epidemic, the typing of pneumococci and the hemolytic streptococcus work could not wait. Major M. C. Stone, M. C., chief of the laboratory service, reports that in the cultures from the nonsuppurative appendixes the hemolytic streptococcus was occasionally found, but most of the cultures were sterile. The suppurative cases showed the pneumococcus, the colon bacillus and the streptococcus, but without evidence of any predominating type of infection. We greatly regret that the exigencies of the epidemic prevented a full study of the relationship between the respiratory infection and that of the appendix.

There is certainly no ground in our findings for closely connecting the attacks of appendicitis, in any direct bacteriologic way, with the epidemic, as one may connect empyema with definite types of pneumonia.

A satisfactory recovery occurred in every case but one. The fatal result was noted in a patient who had been five weeks in the cardiac ward early in 1918 with widely dilated heart and systolic murmur at the apex. His compensation remained so poor that he had been excused from even the morning exercises, which, when taken, exhausted him for the day. The appendix was a long retrocecal one, largely subperitoneal and acutely inflamed, but not such as to lead us to have any special anxiety as to the outcome. Exhausting suppuration occurred, and he died at the end of the first week.

The data that we present are insufficient to justify any exact conclusions as to the influence of the epidemic on the morbidity from appendicitis. Nevertheless, we believe there is firm basis for the opinion that some close relationship exists between the two affections. It is extremely suggestive that on the first day of the influenza attack so many patients showed such definite signs in the region of the appendix as to lead to a diagnosis that proved to be incorrect, assuming our opinion on this point to have been well founded. If this symptomatology was dependent, as we believe, on involvement of the lymphoid tissues of the appendix, we may readily conceive that in many other instances a definite inflammation resulted which eventually demanded operation.

Perhaps we are not far wrong in assuming that the epidemic, characterized as it was by a phenomenal activity on the part of many different pathogenic organisms, gave special opportunity for the development of inflammation of the appendix; but whether by reduction of the general bodily resistance, by exciting a new attack in a chronically affected organ, by its action on the lymphoid tissues, or by an infection through the blood stream or otherwise, does not appear. Certainly some cause lay behind the increase from a percentage of 10.4 for our first year, to a rate of 44.4 for November and December, 1918, in the incidence of appendicitis requiring operation. We wish rather to place these observations on record as a minute part of the history of the great epidemic than to attempt to draw any extensive inferences from such slender data.

POSTMORTEM CESAREAN SECTION FOLLOWING AN INFLUENZAL BRONCHOPNEUMONIA

SUCCESSFUL DELIVERY OF A LIVING CHILD

MAURICE HEPPNER, M.D.
Resident Surgeon, San Francisco Hospital
SAN FRANCISCO

The conditions most frequently calling for a postmortem cesarean section are the sudden death of the mother from traumatism, hemorrhage or eclampsia. In the case in hand, death was the result of a bronchopneumonia following influenza.

At first glance it would appear that a number of abdominal sections might have been done during the recent pandemic of influenza; but as I look back over the records of the San Francisco Hospital, in which, during the past four months, we have handled 108 cases of influenza complicated with pregnancy, I find that in only one case was it thought advisable to do a cesarean section. Thus we find the percentage rather small.

REPORT OF CASE

Nov. 9, 1918, Mrs. L. A., aged 24, was admitted to the hospital, in her third labor. Both her last children are living. She was a woman of about 150 pounds, having done the usual housework. On admission to the ward the patient was in a moribund state, markedly cyanotic and profoundly toxic. As was later learned, she had been sick for six days prior to admission to the hospital. A hurried examination revealed a moderate bilateral basal bronchopneumonia. The fundus of the uterus was found to be 3 cm. above the level of the umbilicus. The fetal heart was readily audible and not greatly increased in rate.

As no consent was to be obtained for the operation, it was determined to wait for the patient's natural decease, and then proceed, if possible, to save the child.

From 3:30 p. m. I sat with two interns at the bedside, until at 6:50 p. m. she was pronounced dead. The fetal heart sounds were becoming less audible, and for the last fifteen minutes were so feeble that they could not be heard with a stethoscope. As soon as it was certain that death had taken place, the section was performed. An incision was made in the midline, extending 1 inch above the umbilicus, and downward to the symphysis, and going through the uterus as hurriedly as possible. The child was found to be toxic and feeble, but with very little effort at resuscitation the child began to cry. The child was not quite full term, weighing 3 pounds 15 ounces. The child lived, but died when 25 days old. The cause of death was croupous pneumonia with pleurisy. Microscopic sections of the lungs show a filling of many alveoli with fibrin, and foci of round cell infiltration with areas of necrosis. The areas were most marked around the smaller bronchioles. There was also an inflammatory deposit on the pleurae. The time elapsing after the mother's death, before the delivery of the child, was in this case about one and a half minutes.

The Buckeye in the Left Hand "Pants" Pocket.—Kansas has an illiteracy rate of 2.7 per cent., and yet there are people not in this class, wearing asafetida bags around their necks, or carrying a lump of camphor in their pockets, or contaminating the atmosphere with garlic or onion breaths as a preventive against influenza! Will the janitor please open the windows wider?—*Bulletin,* Kansas State Board of Health.

FURTHER FACTS REGARDING ANTISCORBUTICS

Scurvy, a disease which once represented a menace of serious moment to large numbers of persons at certain seasons and under certain conditions, when "fresh" foods were not available in sufficient variety or abundance, has returned into prominence in recent years. Experience has shown that while the heating of milk for infant feeding may remove undesirable bacterial dangers from this essential food, it is liable at the same time to destroy certain undefined properties of the diet, in the absence of which scorbutic symptoms arise. Furthermore, under the conditions of food supply enforced in some of the theaters of war, the medical officers have also found themselves confronted with scurvy, both among the fighting units and among the inhabitants of devastated areas.

Quite aside from all theories as to the etiology of the disease, experience has demonstrated effective methods for the cure or the prevention of scurvy. In this country orange juice has acquired a growing popularity as an antiscorbutic supplement to the diet of bottle-fed infants. The difficulties in maintaining a supply of oranges at a price within the reach of all classes of persons concerned have been aggravated by the interference with normal transportation during the period of the war. This has, in fact, occasioned much concern among pediatricians in various centers. The possibility of desiccating or preserving the juice in some way at the sources of supply in order to insure a more dependable distribution of orange juice has encountered the obstacle of uncertainty raised by recent studies on the instability of antiscorbutic properties when vegetables exhibiting them are dried.[1] Thus the desiccation of cabbage seems to deprive it of antiscorbutic potency unless the drying is carried out at low temperatures and with special precautions. Chick and Rhodes,[2] of the Lister Institute for Preventive Medicine in London, have recently found, in searching for possible substitutes for the highly efficient orange juice, that fresh grapes are of little value as antiscorbutics; of the raw vegetable juices examined, raw swede juice proved to be far the most potent, approximating in value to orange juice; the raw juice of carrots was found to be much inferior, and that of beet roots practically negligible in value, so far as acceptable dosage is concerned.

From a practical standpoint the discovery of this potency of swede juice seems to be important because it promises to afford a valuable, inexpensive source of antiscorbutic material. According to the English investigators, the value of swede juice is not markedly inferior to that of fresh orange juice, so that it may be regarded as a satisfactory substitute. Its value approximates ten times that of the raw carrot and more than ten times that of raw beet root juice. Chick and Rhodes add that swede juice has been adopted in some of the English infant welfare centers, and there does not appear to be any drawback to its use in infant feeding. Curiously enough, the swede belongs to the natural order *Cruciferae,* which also includes the cabbage, perhaps the most potent of all antiscorbutic vegetables investigated.

In the case of adults living under conditions in which fresh foods are not available, a belief in the antiscorbutic potency of the juice of the West Indian lime has been cherished for decades. Arctic explorers, ships starting on long voyages without access to land, and expeditions away from sources of appropriate food supplies have been accustomed to be equipped with lime juice preserved in various ways; and there are records to show that vigorous steps were sometimes taken to enforce the actual ingestion of the dosage as ordered. The efficacy of this preventive therapy has been far from universal; and an explanation seems to be afforded by recent investigations, also conducted at the Lister Institute, by Chick[3] and her co-workers, to whom we are already indebted for valuable contributions to the prevention of scurvy. Preserved lime juice was found useless for the prevention of scurvy by the methods employed. The fresh limes have some potency; but it has now been shown that, volume for volume, their juice is only about one-fourth as effective as is lemon juice. Curiously enough, a historical study of the reported cures of scurvy with lime juice shows that the agent employed in several authenticated instances was in reality the juice of the lemon. There are instances of severe scorbutic outbreaks despite the liberal use of lime juice. This demonstrated virtue of the lemon, a fruit so widely employed in the household in modern life, affords an added illustration of the unique value of many items of diet, like certain fruits and green vegetables, for which we pay a high price despite the fact that they give no equivalent return in calories. Instinctively, perhaps, we have come to include in our dietaries articles of food which have a high physiologic value that cannot be measured in the current terms of food units.

SACCHARIN—AFTER THE WAR

The restrictions of trade and the shortage of many important supplies incident to the war have encouraged the production of substitutes in the domain of foods and drugs as well as in other fields of commerce. This has been true in far greater degree in the overseas countries than in America, where the deprivations and interferences have not been so protracted. It has frequently been remarked by those who have familiarized themselves with conditions in Germany during the latter years of the war that the entire population of the Central Empires seemed to be eating, drinking and wearing substitutes most of the time. Some of these will doubtless establish themselves as useful contributions to our mode of living—products of the ingenuity of necessity.

The war has taught us that it is no great hardship to do without certain drugs that were once regarded as next to indispensable. On the other hand, we must be on our guard lest temporary advantages gained for avowed substitutes in times of stress are allowed to become a reason for foisting on a tolerant public products that have no proper place in the everyday life of peace times.

An illustrative case is afforded by the use of saccharin, which has veritably been a gustatory blessing to hundreds of thousands of persons who were unable to secure sugar, on which they were accustomed to depend for insuring the palatability of certain foods. How large the traffic in saccharin, sanctioned by the governments of the nations affected, has been is indicated by the statement of a single British firm which itself furnished 1,785 million tablets[1] to meet the emergency. Having satisfied a need, the manufacturers appear not to be content, like munitions and other war industries, to turn their talents and plants to better uses, but suggest that the great commercial sacrifices made in setting their works into operation to produce saccharin should be rewarded, as it seems, by the permission to continue the traffic under post-war conditions.

Thus a new plea is added to the old arguments of those who wish to foist saccharin on the public. Formerly it was alleged that the chief objectors were the sugar cultivators and manufacturers. "It is true," admits a large producer of saccharin, "that saccharin is without nutritive value, and so it is not recommended as a substitute for sugar in feeding children." He contends, however, that "the highest medical authorities" are fully agreed that it is perfectly innocuous and has no effect whatever on metabolism. It is urged to have a special value in adiposity, and we are assured by this lay expert that many quite healthy persons receiving sufficient nourishment from other foods, and conscious that they are benefited by abstinence from sugar, will henceforth take advantage of the sweetening properties of saccharin.

The referee board to which the saccharin problem was referred in this country several years ago has by no means given a clean bill of health to the chemical. It has merely fixed a lower limit of apparent innocuousness and warned against promiscuously large dosage. There are still plenty of persons in the world who are not children and who do not suffer from either adiposity or diabetes. They need to be protected from the danger, not to mention the deception, of a substitute for sugar which is in no sense a true food. We doubt whether the time has arrived when any considerable portion of the world's population needs to be protected against harm from a wholesome food by the use of a chemical which has no food value and may be definitely harmful.

THE DANGERS OF INHALED DUST

In a widely circulated popular book, entitled "Dust and Its Dangers," which was published about thirty years ago, emphasis was placed on the distribution of bacteria by that form of "matter out of place" which is commonly designated as dust. This was quite appropriate at a time when the widespread distribution and previously unsuspected significance of the micro-organisms were being brought to the notice of the world at large. Since that early period in the development of modern bacteriology, preventive medicine has begun to direct attention to quite different aspects of the dust menace. The recognition of the possible pathologic effect produced by the inhalation of minute, nonliving particles of matter is by no means new. Clinical observations on the subject have long been on record; and the question as to whether certain pigmentations of the lung are due to extraneous particles or to pigmented tissue products has been debated since the days of Virchow. Nevertheless it has been due to the demands of industrial hygiene, perhaps more than any other stimulus, that careful investigation has been renewed in this field of inquiry.

It is known from industrial experience that there are distinctions between dusts of different origins, so far as their effects after inhalation are concerned. Dust rich in silica, such as is encountered in the gold mines of the Transvaal and in many potteries, is admittedly dangerous. On the other hand, in comparison with flint dust, it is believed that coal dust and shale dust are relatively harmless. An investigation conducted by Mavrogordato[1] for the English Medical Research Committee under the national insurance act has thrown some light on the distinctions just referred to. Specifically formulated, the question may be thus presented: Since it may be regarded as established that all forms of dust enter the lungs, why is it that some, such as coal, are relatively harmless, while others, such as flint, are deadly?

---

[1] According to the annual report of Boots Cash Chemists, Ltd., in the London Observer, Jan. 19, 1919.

The answer appears to lie in the fact that some dusts are eliminated much more readily than others: at any rate, when the exposure is a moderate one. After intense dusting, all the dusts appear to produce much the same effects, both immediate and remote. But under the more usual industrial conditions, it seems, from Mavrogordato's investigations, that dusts which make mischief are dusts that accumulate. Coal and shale, for example, are taken up by cells which are quickly shed and consequently do not set up processes which block lymphatics. These cells frequently break down, and masses of dust are to be seen on the surface of the alveolar walls. Plugs of mucus, dust cells and dust find their way out of the lungs through the bronchi, though some dust may leave indirectly by means of the lymphatics. In other words, the more readily eliminated dusts produce a marked initial reaction with much shedding of epithelium. The flint dust and crystalline silica, by way of contrast, are taken up by cells that tend to remain in situ. They form plaques which persist, and the shedding of the epithelium is far less conspicuous. Cell proliferation is much more marked, and fibrosis may ensue. Permanent lesions are liable to be produced.

Since many persons are engaged in essential employments that compel them to pass a large portion of their time in dusty atmospheres, the question of ameliorating the conditions and averting the dangers is a serious one. Even if dust rarely kills, aside from producing considerable fibrosis of the lung it may predispose the individual to pulmonary tuberculosis. Dilution of the dust seems, by itself, to offer little promise of help in the case of the more dangerous sorts; for the dose must be extremely small in the case of such particles as flue dust and silica, if accumulation is to be avoided in the lung. There is somewhat greater prospect of relief in the observation that dusts which produce an initial reaction of epithelium shedding tend to carry the more inert forms out with them. Thus some admixture of coal dust may act as a protector when the more deadly dusts are inhaled; in fact, such chance combinations may explain the apparent immunity experienced by certain workers with flint and silica dusts. Coal dust has its special industrial risks, since it is responsible for explosions in the coal mines. This danger can be reduced to a minimum by mixing coal with inert dusts. Hence Mavrogordato remarks that the ideal would be to stop colliery explosions by adding flint and to stop phthisis by adding coal, thus holding a tenace over providence.

Current Comment

DIETETIC VALUE OF NUTS

The war has taught us to appreciate many things which were by no means new but which had remained in partial oblivion because of the characteristic inertia of man toward a change in his traditional habits. In illustration may be cited the neglect of nuts as articles of food. Although many persons eat liberally of nuts and the vegetarians have long regarded them as a sort of staple in the diet, we venture to believe that most Americans at least are wont to class them as relishes or accessories. The suggestion to use nuts more liberally often meets the objection that they are not well digested and are likely to give rise to alimentary discomfort. Actual experiment has demonstrated, however, that the charge of inherent indigestibility is not borne out,[1] provided the nuts are consumed under proper conditions. The reported distress attending their use is probably due to inadequate mastication, so that larger masses of an impervious vegetable product are ingested; or they are eaten after an already abundant meal. Nuts are in fact highly concentrated foods, consisting essentially of proteins and fats. Chestnuts alone are rich in carbohydrate, in the form of starch, and are poor in fats. It should be borne in mind, by way of comparison, that the 100-calory portion of most nuts is very small; for example, from twelve to fifteen almonds furnish such an equivalent of food fuel. Remembering that proteins are no longer to be judged solely by their quantity, since a quality factor has been demonstrated by current methods of investigation by direct feeding to be of nutritive significance likewise, it may be asked whether the nut proteins take a reputable rank in this respect. It is probably fair to say that proteins from plant sources do not receive the dietary respect that is accorded to those of animal origin. The proteins of meat, eggs and milk are put into a superior category by a sort of popular consent, when they are contrasted with those furnished by the cereals, legumes and other green vegetables. Some surprise was created, therefore, by Hoobler's[2] experimental evidence of the high value of nut proteins in relation to human milk proteins. A similarly favorable report has just been rendered by Morgan and Heinz[3] from observations they have made on man at the University of California. The protein of almond meal was noted to have a "biologic value" superior to that of wheat gluten, itself a well utilized cereal protein source. Such carefully determined facts must be weighed against popular prejudices in considering the availability of nuts in any regimen. Even though they may not be demanded under the conditions of ordinary diet, there are not a few occasions when carbohydrate-free foods of the protein-fat type would form a welcome addition to the curtailed list that some disease or idiosyncrasy may have occasioned.

RESEARCHES AND REMEDIES IN RURAL SANITATION

In 1914 the U. S. Public Health Service began a special study, intensive in character and extensive in scope, of rural sanitation. Of this study, which is still in progress, Dr. L. L. Lumsden, now an assistant surgeon-general of the service, has been from the start in direct and responsible charge, and his report on three years' work in thirteen states and fifteen counties, ranging from Maryland to Kansas, has just appeared as Public Health Bulletin 94. In spite of the excessive urbanization of the last century, America is still largely rural. Moreover, city and country are more closely bound together than some realize, since, as Dr. Lumsden truly says, mosquitoes and flies regardlessly cross state lines, county lines, city lines, town lines and line fences between farms, while "the average large American city obtains its milk, vegetables and fruits from as many as five or six different states," and "insanitary conditions at farm homes in one state are often responsible for contamination of milk or other foods, causing extensive outbreaks of disease in cities, towns, villages or country neighborhoods in other states." City conditions likewise react on rural populations, through the rural resident homeward bound, the city dweller seeking refreshment in the country, and in many other ways. Hence the obvious importance of rural as well as city sanitation, the sanitary chain being never stronger than its weakest link. One of the worst defects of modern life is its want of leisure, and because of this there is danger that Dr. Lumsden's really remarkable report will fail to be read and studied as it deserves to be. For thoroughness of inquiry, for insight into a primitive state of American sanitation, and for a comprehension of the fundamental sanitary problems of our contemporary civilization, no similar report has been available. The conditions revealed by Dr. Lumsden's researches are perhaps not very different from what might have been anticipated, but it was indispensable to have them solidly established and not merely assumed or accepted. It is, however, the remedies devised, the improvements introduced, and particularly the propaganda found effective that especially excite our interest and admiration. Best of all are the striking results obtained in the direction of health and sanitary improvement and the prospect of their essential permanence. The report is illustrated by numerous and often ingenious charts and diagrams, which adorn Dr. Lumsden's story and point his sanitary tale, carrying the final conviction that, after all, it is simple, old fashioned—yet scientific—cleanness that is the foundation of our modern sanitary superstructure. Physicians should familiarize themselves with the details of this absorbing story of twentieth century sanitary research.

"FIGURES NEVER LIE"

Next to the "patent medicine" exploiters, no class has commercialized the recent epidemic of respiratory disease, or played on the public's fears more skilfully, persistently, and unscrupulously, than the various "drugless healing" sects and cults. Following the classic course, "lies, d—n lies and statistics," the latest move in this advertising campaign is the publication of statistics. These figures purport to show the vast improvement in the treatment by chiropaths, naprapaths, naturopaths, or some other "paths," over that given by scientific medicine, in dealing with the "flu," and its sequelae. Thus we find a newspaper solemnly telling its readers that the "so-called drugless doctors of New York City" have announced that during the recent epidemic they "did not lose a single case." This "announcement" the editorial writer characterizes as "astounding" and draws the "appalling conclusion" that most of the people who have died during the recent epidemic have actually been killed by practitioners of medicine! Several other equally startling deductions are drawn by the same writer from the bait so frankly cast and so voraciously swallowed, hook, line and sinker. Those who accept without question the "statistics" of the "drugless healers" to the effect that "they didn't lose a case," ignore the rather patent reasons why the empiric avoids this unpleasant catastrophe. They forget that many people have gone to such "healers" who never had the disease, self-diagnosed as influenza; they brush aside the fact that those who really had it forsook the quack as soon as they realized their danger and invoked the aid of medicine, and finally they ignore, or possibly do not realize the further fact that, it being illegal for the "drugless healers" to sign death certificates, these gentry make it a routine practice to abandon to the medical profession all cases that have reached a serious stage. All of these actualities obviously invalidate the "statistics," even supposing they were honestly collected. "In all my years of service," said the ancient driver of the four-wheeler, "statistics show that I have never lost a single passenger by drowning!" "Although I have been crossing the Atlantic for thirty years," vouchsafed the captain of the ocean greyhound, "I can prove by incontrovertible statistics that not one of my passengers was ever run over by a taxicab while in my charge." Wonderful are the uses to which statistics can be put!

WHAT IS "PTOMAIN" POISONING?

The term "ptomain" poisoning has become a cloak for ignorance. Jordan[1] says that "ptomain poisoning is a convenient refuge from etiologic uncertainty." In fact, any acute gastro-intestinal attack resulting from a great variety of causes is apt to be called "ptomain" poisoning. Selmi, in 1873, first used the word ptomain (from πτῶμα, a corpse) to include the poisonous products of putrefaction which gave the reaction then looked on as characteristic of vegetable alkaloids. From the time of Selmi, when ptomains were regarded as animal alkaloids, our conception of these substances has changed markedly. The last attempt to give precision to the term was by Vaughan,[2] who defined ptomains as intermediate cleavage products of protein decomposition. Rosenau and his associates[3] at Harvard have been searching in vain for the past year and a half for ptomains that might cause gastro-intestinal or other symptoms. Split products of protein putrefaction are readily isolated. Some of these products have physiologic activity, but none of them thus far have been demonstrated to be poisonous when taken by the mouth. The so-called ptomains isolated and described by Selmi, Nencki, Brieger, Schmiedeberg, Faust and Vaughan were usually obtained from putrid organic matter that had decomposed past the point at which it would be used as food. Furthermore, most of these substances were tested by injecting them subcutaneously or intravenously into animals. Many substances are poisonous when thus introduced parenterally, though they may be harmless by the mouth. Again, many of the so-called ptomains isolated and described have since been shown to contain impurities. Chemists are now seldom confident of the purity of protein fractions, even when obtained in crystalline form. The chemical search for split protein products as the cause of "ptomain" poisoning has practically been abandoned. Most of these split products are amins, which are either not poisonous at all, or no more so than their corresponding ammonia salts. The chemical resemblance between muscarin and cholin has directed the work toward the phosphatids, but thus far this line of research has not helped solve the puzzle of "ptomain" poisoning. Chemists avoid the use of the word ptomains, for the reason that it lacks precision. This is a curious instance of the popular use of a technical term that sounds well, but means little. Only clinicians cling to it as a convenient refuge. Ptomain is a term for chemical substances of uncertain origin, unknown nature, and doubtful existence.

Electric Diagnosis of Internal Ulceration.—L. Freund writes to the *Deutsche medizinische Wochenschrift*, **44**:1345 (Dec. 5) 1918, to call attention to the information that is to be derived from the sharp local pain felt when a weak faradic current passes through any excoriation. He utilized it to detect any break in the skin in his hands before operations. He dipped his hand in the fluid of the hand jar of the "four cell electric bath" for arms and legs. The twinge of pain from even a hangnail showed at once the points to be protected with collodion. The method is applicable to the body cavities, stomach, bladder, rectum and vagina. For the stomach, he introduces a fine copper wire inside the stomach tube into the stomach, and passes a roller electrode over the surface of the body outside. The patient first drinks the barium contrast suspension, as roentgen examination usually is done at the same time. This thick suspension prevents any injury from the wire guide in the rubber tube. In sixteen persons thus tested, five complained of sharp pain at one or more points in the anterior wall of the abdomen. One of this group had a laparotomy later, and evidences were found of a healed invagination. The nine who responded negatively to the test were all clinically sound except one man with an atonic sagging stomach.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending February 28, the Medical Corps contained 21,545 officers, a decrease from the previous week of 406. The Medical Reserve Corps contained 783 officers. The total number of medical officers discharged since the beginning of the war is 12,037

Severely Wounded

The following medical officers have been reported as having been wounded severely: Eugene Robert Van Meter, Lieut., St. Louis; Harlow R. Connell, Lieut., Roanoke, Va.; Fred Vosburgh, Lieut., Castelton-on-the-Hudson, N. Y.; Frank Petty Hixon, Capt., Pensacola, Fla.; Harold B. Eaton, Lieut., Boston; Harry A. Seigall, Lieut., Hartford, Conn.; Lucius L. Handly, Lieut., Houston, Texas; Guy H. Jacobson, Lieut., Wayne City, Ill.

Weekly Bulletin A. E. F.

Feb. 3, 1919

PROMOTIONS

On Jan. 16, 1919, the chief surgeon forwarded to general headquarters a list of recommendations for promotion, including eighty-five lieutenant-colonels to the grade of colonel, 282 majors to the grade of lieutenant-colonel, 932 captains to the grade of major and 2,457 lieutenants to the grade of captain. The Weekly Bulletin points out that this is a long list because there have been great and unfortunate delays in making promotions in the Medical Department of the A. E. F., and it represents an accumulation to fill long existing vacancies. There will still remain the following vacancies: 241 in the grade of colonel, 293 in the grade of lieutenant-colonel, 1,151 in the grade of major and 1,323 in the grade of captain. In a general discussion the chief surgeon explains the reason for delays in promotion up to this time. Much of the Bulletin is devoted to the endeavor being made to control venereal diseases.

STATISTICS ON DISEASES IN THE A. E. F.

The greatest number of A. E. F. patients in base and camp hospitals and convalescent camps in France and England was in the week ending Nov. 7, 1918, when a total of 190,888 beds were occupied by sick and wounded. Of these beds 39,778 were classed as emergency beds.

On the day the armistice was signed (November 11), there were occupied or available a total of 209,134 normal beds, or beds spaced one per three linear feet of Adrian barracks or equivalent space in procured buildings. In addition, there were available space and equipment for emergency beds for 74,399 more patients, or a total of 283,533 normal and emergency beds.

On this date, there were in operation 153 base hospitals, sixty-six camp hospitals, and twelve convalescent camps.

Between November 11 and December 5, the number of normal beds was increased to 223,257, with an emergency expansion up to 296,835.

Either in hospitals actually operating at the time of signing the armistice or in buildings leased for hospital purposes or provided for in new hospital buildings authorized or under construction, there was an eventual normal bed capacity of 423,722 with an emergency expansion up to 541,000 beds.

On Jan. 23, 1919, there were 97,458 patients in base and camp hospitals and convalescent camps, of whom 18,214 were Class A men awaiting evacuation (actual patients, 79,244). There are also 33,171 patients (14,462 medical and 18,659 surgical) ready to be evacuated.

In the evacuation, mobile and field hospitals of the three armies, there were 9,765 patients at the same time.

TYPHOID AND PARATYPHOID

Cases of typhoid and paratyphoid have been reported in several organizations. In some, carriers have been found, and instructions have been issued to revaccinate all men in every organization in which two or more cases of typhoid or paratyphoid have occurred. For the first time in two months the week of February 3 showed a definite and considerable reduction in the existence of typhoid and paratyphoid.

The rates of the communicable diseases for this season of the year are considered to be creditably low. The annual rate per thousand, venereal disease, for the whole A. E. F. is 36.9, certainly a creditable record.

HONORABLE DISCHARGES, MEDICAL CORPS, U. S. ARMY

NOTE.—In the following list, L. signifies lieutenant; C., captain; M., major; L. C., lieutenant-colonel; Col., colonel, and B. G., brigadier-general.

ALABAMA

Belle Ellen—Nettles, R. (L.)
Huntsville—Westmoreland, H. D. (C.)
Livingston—Davidson, M. T. (L.)
Scottsboro—Boyd, H. (C.)
Selma—Harper, W. W. (C.)
Troy—Weedon, H. M. (M.)

ARIZONA

Douglas—Wright, F. T. (M.)

ARKANSAS

Hot Springs—Tarkington, G. E. (L.)
Searcy—Tapscott, S. T., Jr. (L.)

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Acting Asst. Surg. L. L. SOLOMON, proceed to Washington for conference relative to venereal disease control measures in Kentucky.

Special Investigator C. W. METZ, proceed to Washington for conference relative to investigation after returning to work of the Carnegie Institution.

Sanitary Engr. H. H. CROHURST, relieved at Fort Worth, Texas. Proceed to Wilmington, N. C., for studies of sewage disposal.

Asst. Sanitary Engr. S. B. BOWNE, proceed to Memphis, Tenn., for completion of records of Service work at Millington.

Asst. Sanitary Engr. W. A. HARDENBURG, relieved at Fort Worth, Texas, proceed to Wilmington, N. C., for studies of sewage disposal.

Scient. Asst. C. W. CRANE, proceed to Hattiesburg, Miss., via Louisville, Ky., to take over the operations of the venereal disease clinic.

Supervising Nurse ANN DOYLE, proceed to New York, N. Y., and Elizabeth, N. J., for the purpose of presenting the subject of venereal disease control before the Lincoln Hospital and Home Training School for Nurses on March 18, 1919, and the annual meeting of the New Jersey State Nurses' Association April 1, 1919.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Influenza.—According to the report of Dr. William C. Hassler, health officer of San Francisco, out of an appropriation of $50,000 for combating influenza in the city, $35,293 was spent for that purpose. The secretary of the state board of health, Dr. W. F. Kellogg, late in February sent out circular letters to local health boards in an endeavor to determine whether there was a third wave of epidemic influenza throughout the state. The indications were that there were only local rises in the number of cases in widely scattered communities.

FLORIDA

Venereal Clinic Opens.—A venereal clinic was opend at the old City Hospital, Miami, January 24, by the state board of health and the United States Public Health Service. The clinic is open from 8 to 9 in the morning, and 5 to 6 in the evening.

Automobile Service Agent Victimizes Physicians.—We are informed by Dr. James V. Freeman of Jacksonville that an agent giving the name of Smith and claiming to represent an automobile service company of St. Louis is proffering to physicians membership in this organization at $50. Dr. Freeman wrote to the headquarters of the association and finds that there is no such concern within the knowledge of the postal department.

ILLINOIS

Dispensary for Decatur.—Dr. George G. Taylor, of the division of social hygiene, state department of health, Springfield, has arranged for the opening of a dispensary in that city for the treatment of venereal diseases. The equipment will be furnished by the department of health, and the dispensary will be operated by the city under state supervision.

Anniversary Meeting.—The seventy-first anniversary meeting of the Peoria Medical Society was held, February 17. Dr. Rolland L. Green, Peoria, president, acted as toastmaster; names of forty-six members of the society who have served during the war were printed on the program as an honor roll, and the addresses made dealt with the bravery and sacrifices of American soldiers.

Memorial for Soldiers.—A movement for a hospital rather than a community house as a soldier's memorial for Highland Park was advanced, February 27, at a meeting of 150 women of that suburb, at which it was agreed by the hospital authorities that the hospital be rededicated as a memorial, provided enough money is raised to build an annex for the treatment of contagious disease patients.

Influenza.—A second epidemic of influenza was reported from Duquoin, February 28, where it was said there were 300 cases reported, with a number of deaths; fifty cases were reported from Sunfield in the same neighborhood, and many cases among the farmers. The state health department reports influenza as leading in the number of contagious disease cases, the number for the week ending February 22 being 1,680, of which Chicago had 498.

Illegal Practitioners Sent to Jail.—Jeff Mardon, East St. Louis, was arrested by an inspector of the department of registration and education for practicing medicine without a license. He was fined by the court but was unable to pay it. He was then committed to the county jail for two months.——Dr. J. J. Vizgird of St. Louis was arrested by the department of registration and education for practicing medicine in Illinois without a license. Vizgird was unable to give bond and is now in jail awaiting trial. This is the third time Vizgird has been in the court in St. Clair County for practicing in Illinois without a license.

Chicago

New Passavant Hospital.—A new Passavant Hospital to cost about $1,000,000 is to be built to replace the present hospital at Superior and LaSalle streets.

Hawkins in Jail.—The self-styled divine healer known as the "Rev. Dr." Walter Hawkins was again taken into custody, February 21, on a charge of violation of the medical practice act. Hawkins now has five such charges pending against him.

Personal.—Harry D. Orr, Lieutenant-Colonel, M. C., U. S. Army, formerly commanding officer of the 108th Sanitary Train, 133d Division, has been appointed division surgeon of the Thirty-Third Division, which is located in the Duchy of Luxembourg near Treves, Germany, in reserve for the Third American Army.——Walter J. Sullivan, Lieutenant, M. C., U. S. Army, who was severely wounded last May, after four months in a hospital in London was returned to Marseilles, and has been reassigned to duty with the British Expeditionary Forces.——Maurice L. Goodkind, Dallas Phemister, Samuel C. Plummer and William McI. Thompson, Majors, M. C., U. S. Army, and George H. Miller and William F. Bernart, Captains, M. C., returned from abroad on the U. S. S. *President Grant,* February 26.——Carey Culbertson, Major, M. C., U. S. Army, who has been on duty at Camp Pike, has been discharged and reached Chicago, March 2.——Andrew J. Lyons, Major, M. C., U. S. Army, has returned from abroad.——Dr. Samuel J. Walker, who went to Greece with the American Red Cross Medical Mission last year, is now on duty in the remote districts in Macedonia.——Dr. Tracy H. Clark has been elected president of the medical section of the National Fraternity Congress of America.——Joseph A. Capps, Lieutenant-Colonel, M. C., and Ray H. Davies, Major, M. C., U. S. Army, have returned from abroad.——Herbert H. Frothingham, Major, M. C., U. S. Army, who has been on duty at Fort Des Moines as chief of the medical service for more than a year, has returned to Chicago and resumed practice.

KANSAS

Personal.—Dr. Dellett E. Bronson, Olathe, has been appointed physician of Johnson County.——Dr. Samuel J. Herrick, Everest, announces his retirement after thirty years of practice.

Appropriation Asked.—Senator Milligan, Garnett, has introduced into the Kansas legislature a bill for an appropriation of $25,000 for the purchase of vaccine to aid in the control of epidemics, and $25,000 additional for the state board of health, to be used in controlling epidemics in any way it may be deemed best.

New Officers.—At the annual meeting of the Barton County Medical Society, held in Hoisington, Dr. Horace C. Embry was elected president, Dr. Thomas J. Brown, vice president, and Dr. Benjamin S. Pennington, secretary-treasurer, all of Hoisington.——The Leavenworth County Medical Society at Leavenworth, February 10, elected Dr. Charles J. McGee president; Dr. Clarence C. Goddard vice president, and Dr. Jacob L. Everhardy secretary-treasurer, all of Leavenworth.

Cost of Preventable Disease.—Dr. John J. Sippy, Topeka, epidemiologist of the Kansas State Board of Health, announces $11,000,000 as the sum which preventable diseases cost the state of Kansas during 1918. These diseases were typhoid fever, tuberculosis, smallpox, scarlet fever and diphtheria. The state board of health is endeavoring to convince the legislature that it should divide the state into forty health districts, each supervised by a competent official, who will devote his entire time to the work.

Proceedings in Paternity.—A bill entitled "Proceedings in Paternity" which is of special interest to physicians has been introduced in the Kansas legislature by Dr. Lydia Allen DeVilbiss, director of the division of child hygiene, state board of health, Topeka. The bill provides that any physician, nurse, midwife or other attendant on the birth of a child born out of lawful wedlock shall, under penalty of misdemeanor, report the fact in writing within ten days to the juvenile court, whereupon it becomes the duty of the court to institute inquiry proceedings. In this manner, the responsibility for establishing the parenthood of a child born out of lawful wedlock is shifted from the girl-mother to the state of Kansas. The man found by a judge to be the father of the child is charged with the same responsibility for the maintenance, education and care as is now imposed or shall in the future be imposed on a father of a child born in lawful wedlock of like age and capacity.

MARYLAND

Personal.—J. Albert Chatard, Major, M. C., U S. Army, Baltimore, chief of the medical service at Base Hospital No. 78, which was located near St. Mihiel, France, has returned to the United States and is now stationed at Camp Dix, awaiting discharge.——Lloyd B. Whitham, Captain, M. C., U. S. Army, a member of the Johns Hopkins Unit and chief surgeon of the advanced eye center of the American Expeditionary Forces, has returned to his home in Baltimore.——Richard F. Kieffer, Major, M. C., U. S. Army, Hagerstown, who was in command of Base Hospital No. 18 (the Johns Hopkins Unit), Louis J. Casamajor, Major, M. C., U. S. Army, and George R. Dunn, Captain, M. C., U. S. Army, also of Base Hospital No. 18, are to be retained for further service. The remainder of the staff have received their discharge.——Peregrine Wroth, Captain, M. C., U. S. Army, Hagerstown, who has been with the medical division of the U. S. Army in France, has arrived in this country and is stationed at Camp Dix, N. J.

MISSOURI

Fire in Hospital.—A disastrous fire almost destroyed St. Mary's Hospital at Jefferson City, February 20, endangering the lives of patients and nurses. The citizens have begun steps for immediate reconstruction of the building.

Health Bill.—The state board of health has introduced a bill in the legislature to give the board broader powers, especially in regard to communicable diseases and better control of county health officers, and the children's code commission has prepared a series of bills which, if passed, will establish adequate measures for the intelligent conservation of child life. In his message to the legislature, Governor Gardner has advocated the passage of these measures. At present the Missouri board cannot participate in the federal appropriation for the control of venereal diseases because the board of health cannot legally declare what diseases are communicable or require reports.

Personal.—John F. Binnie, Lieutenant-Colonel, M. C., U. S. Army, Kansas City, is reported to be en route from France. Colonel Binnie was in charge of Base Hospital Unit 28 when he was sent overseas, but was later made chief consulting surgeon of the Third Army Corps, and afterward appointed chief consulting surgeon for all the base hospitals at Limoges.——Dr. Wilson J. Ferguson, Sedalia, has been reappointed a member of the state board of health in the place of Dr. Andrew W. McAlester, Columbia. Dr. Ferguson was president of the state board of health when he accepted a commission in the Army, and Dr. McAlester was appointed to fill the vacancy thus created. On the return of Dr. Ferguson, Dr. McAlester resigned and requested that Dr. Ferguson be reappointed to his old position.

Volunteers for Medical Inspection.—Thirty-two physicians in Kansas City have volunteered their services for medical inspection of the children in public schools. Many of the citizens of Kansas City, especially the mothers with enlightened ideas of modern methods of preventing disease, have repeatedly petitioned the local board of health to establish a system of medical inspection of schoolchildren, but all efforts in this direction have proved futile. It is said that the parochial schools provide medical inspection for their pupils. Some work has been done in public schools through the generosity of private citizens and the voluntary cooperation of members of the Jackson County Medical Society, but as yet the city authorities have not assumed the responsibility that should be theirs in protecting the children and the general public from the spread of communicable diseases originating among schoolchildren.

St. Louis

Military Medicine Meeting.—The meeting of the St. Louis Medical Society, March 1, was devoted to military medicine. Dr. Arthur W. Proetz spoke on Base Hospital No. 21 in France. Dr. Robert E. Schlueter considered United States base hospitals. Dr. Stanley S. Burns described an evacuation and field hospital. Dr. Malcolm A. Bliss detailed the work in the recruiting depot of the line officers' training camp.

Chiropractors Arrested.—Four chiropractors were arrested in St. Louis, February 28, at the instance of the health department, charged with unlawfully practicing as physicians. The representatives of the health department assert that they consulted the four chiropractors on different dates and that each member of the fraternity of spinal manipulators diagnosed a malady although both of the investigators were in perfect physical condition, and charged fees for their medical opinion.

NEW YORK

Meningitis Carrier Detected.—Officials of the state department of health, Albany, believe they have prevented a serious outbreak of cerebrospinal meningitis by the prompt detection and isolation of a meningitis carrier. The carrier was a soldier who returned a short time ago to his home at New Baltimore. Soon after his return, his niece was stricken with cerebrospinal meningitis, and the soldier was the only one of the contacts to respond positively to the test. He was accordingly isolated, and no other case of the disease developed.

Postgraduate Course in Infectious Diseases and Public Health.—Arrangements have just been perfected by which a new course in infectious diseases and public health is being given under the joint direction of the Albany Medical College and the New York State Department of Health. The new course started, March 5, and is open both to physicians and health officers, but will have no connection with undergraduate instruction. The course will be under the general supervision of Dr. Charles C. Duryee, Schenectady, sanitary supervisor, state department of health, Albany, to whom all correspondence regarding the course should be addressed. The fee is $25, payable in advance, or in monthly instalments if desired. Those who have completed any of the various courses of instruction for health officers, either at Albany or elsewhere in the saate, are invited to attend the course at a nominal fee of $5. Attendance of one day weekly during March and April, and one and a half days during May and the first two weeks in June, will be required. On completion of the course and a satisfactory examination, a certificate will be issued.

Sanitary Supervisors' Conference.—A conference of the sanitary supervisors with the directors of divisions of the state department of health was held at Albany, February 25, 26 and 27. At the first meeting Dr. Harry A. Bray, acting superintendent of the New York State Hospital for Incipient Tuberculosis at Raybrook, gave an address on the best methods of diagnosing incipient tuberculosis; Dr. Joseph S. Lawrence, chief of the bureau of venereal diseases, discussed pneumonia serum and its administration, and Dr. James C. Ayer, of the same bureau, demonstrated the administering of arsphenamin. In the evening a talk was given at the Elk's Club on syphilis and gonorrhea by Dr. Frederick S. Honsinger, Syracuse, of the bureau of venereal diseases, the talk being followed by a presentation of the film "Fit to Win." On the second day the directors of divisions discussed their problems and future plans so far as they were related to the work of the sanitary supervisors. The organization of health conservation committees was also taken under consideration. In the afternoon a conference was held between the supervisor of public health nurses and the nurses of the department. A second conference also was held between the orthopedic surgeon of the department and the infantile paralysis after-care staff. On the third day a report was given by Dr. Charles C. Duryee, Schenectady, on his work of scoring health activities in cities. This report was followed by a history of influenza epidemics by Dr. Otto R.

Eichel, Albany. A conference was also held between the chief of the bureau of venereal diseases and the members of his staff.

New York City

Harvey Society Lecture.—The fifth lecture of the Harvey Society series will be delivered at the New York Academy of Medicine, at 8:30 p. m., March 15, by Col. F. P. Underhill, on "War Gases."

Medical Inspectors Form Organization.—The medical inspectors of the health department met in the county court house, Manhattan, February 21, and effected temporary organization as a council of the New York Civil Service Society. Dr. Maria M. Vinton, Richmond Hill, was chosen chairman, Dr. Maude Glasgow secretary, and Dr. Theodore A. Lehmann treasurer.

Fund to Perpetuate Dr. Cragin's Follow-Up Work.—In order to perpetuate the work of Dr. Edwin Bradford Cragin in connection with the Sloane Memorial Hospital, an organization has been formed to raise $100,000 for the purpose of enlarging and extending the social service activities of the hospital. Dr. Cragin developed the method of caring for maternity and other patients after they had left the hospital, and made this part of the work possible largely through his own contributions, augmented by gifts from grateful patients. The endowment fund which it is now proposed to raise is in the hands of Henry K. McHarg, at 40 Wall Street.

Personal.—Dr. Stephen Smith, for thirty years a member of the state board of charities, celebrated his ninty-sixth birthday anniversary, February 19.——Dr. Herman Seidler, Brooklyn, who pleaded guilty to a charge of speeding, January 31, was fined $100 and sentenced to ten days in jail, was granted his freedom, February 3, and released on a bail bond of $250, pending an appeal of his case to the county court.——Lieut.-Col. Walter C. Montgomery, surgeon of the Twenty-Seventh Division, formerly the New York National Guard, and Lieut. Lee A. Hadley, Syracuse, have received divisional citations for meritorious conduct during engagements in Belgium and France.——Dr. James Alexander Miller has had conferred on him by the French government the decoration of a Chevalier of the Legion of Honor in recognition of his service in connection with the campaign against tuberculosis conducted by the Red Cross and the Rockefeller Foundation.——Dr. John A. Ferguson of Brooklyn has been appointed medical examiner with the municipal civil service commission.

Opposition to Health Insurance Bill.—At the meeting of the Medical Society of the County of New York, February 24, the committee on health insurance, after having conferred with both professional and lay persons interested in the subject, offered a number of amendments to the Donohue bill for the consideration of the society, but in doing so declared that it was to be distinctly understood that it in no wise committed itself either in favor of the Donohue bill or of the scheme of compulsory health insurance as a whole. It simply presented these amendments to the bill in order that if some such bill was enacted into law the interests of the medical profession might be properly safeguarded. The society adopted these amendments but made it clear that it had not withdrawn its condemnation of compulsory health insurance as a whole.——On the same evening the physicians, dentists and pharmacists of Brooklyn, at a mass meeting of the various societies held under the auspices of the Kings County Medical Society, passed resolutions unanimously opposing the Donohue bill.——The Bronx County Medical Society has also gone on record as strongly opposed to the measure.

OHIO

Arrested on Drug Charge.—Dr. Moritz Lowenthal and H. L. Treat, managers of the Rest Cure Sanitarium, Cleveland, are said to have been arraigned before United States Commissioner McGuire, February 13, on a charge of illegally possessing morphin. Federal agents are said to have raided the sanatorium and confiscated narcotics valued at $30,000.

State Society Meeting.—The seventy-second annual meeting of the Ohio State Medical Association is to be held in Columbus, May 6, 7 and 8. The forthcoming convention is expected to be the largest in point of attendance and interest in the history of the Ohio state association. A number of committees are already at work in planning the program. Among the interesting features which are being planned in connection with the exhibition will be scientific exhibits by the state department of health, the Ohio Board of Administration, the Ohio School for the Blind, and the National Society for the Control of Cancer.

Personal.—Dr. Oscar H. Sellenings, who was appointed health officer of Columbus, February 15, was removed after a brief tenure of office, February 19, when it was ascertained that he was violating the state health law by serving as health officer while still a member of the state board.——Dr. William L. Dick, Columbus, is serving as health officer until a successor to Dr. Louis Kahn is elected.——Dr. Charles W. Hedrick, Willard, is reported to be seriously ill with septicemia.——Dr. Charles P. King, Columbus, was stricken with cerebral hemorrhage, February 11.

Tuberculosis Instruction to Physicians and Nurses.—The Ohio State Sanatorium, Mount Vernon, announces that courses of instruction will be conducted at the sanatorium in June, and that physicians and visiting district public health and tuberculosis nurses will be given the benefit of the results obtained at the institution, and this without expense. June 9 to 14 will be devoted to special lectures and courses of instruction to nurses on the subject of public nursing as it effects the tuberculosis situation in Ohio, and the two weeks following, from June 16 to 28, will be open to the medical fraternity for special instruction courses that will embrace twenty lectures, taking in every phase in the history and treatment of the disease. In addition to the regular staff of nurses and physicians at the sanatorium, a number of specialists will assist. Dr. Stephen A. Douglass, superintendent of the sanatorium, has just returned from Italy, where he has been for six months as a member of the American Red Cross Commission, and during his absence Dr. Jay D. Thomas has been medical superintendent. The staff of the sanatorium also includes Drs. Louis Mark and Frank M. McCafferty.

PENNSYLVANIA

Conference of Industrial Physicians.—The eighth conference of Industrial Physicians and Surgeons, held under the direction of the Pennsylvania Department of Labor and Industry, will convene at the William Penn Hotel, Pittsburgh, March 14. The chief topics of discussion are: "Traumatic Hernia and the Compensation Board"; "How the Industrial Physicians and Our State Department of Health Can Best Cooperate"; "Carbon Monoxid Poisoning—Its Prevention and Treatment"; "Sprained Back and Flatfoot"; "Health Hazards in the Manufacture of Dyestuffs"; "How the Industrial Physicians Can Help in the Campaign Against Venereal Disease," and "Health Insurance, Its Disadvantages and Advantages."

Personal.—Dr. Howard L. Hull of Camp Hill, Cumberland County, medical officer of the U. S. Army, has been appointed chief medical inspector of the state department of health.——Joel T. Boone, Lieutenant-Colonel, M. C., U. S. Army, Pottsville, regimental surgeon to the Sixth Marines, who received the distinguished service cross with two additional bars for citations, has returned to his home.——Dr. John N. Sprowles, Claysville, second vice president of the Medical Society of the State of Pennsylvania, was seriously injured, February 21, when his automobile went over an embankment near Taylorstown, sustaining a fracture of the left hip and laceration of the left knee, and is under treatment at the City Hospital, Washington.——Dr. Torrance John Hanlon, Captain, M. C., U. S. Army, Donora, who was decorated by King George of England in December last, for conspicuous bravery, has returned to the United States and is on duty at a government hospital near Pittsburgh.——Dr. Sidney A. Slater has resigned as superintendent of the Grand View Sanatorium, Oil City, to become superintendent of the Southwestern Minnesota Sanatorium, Worthington, Minn. This sanatorium was established by the counties of Rock, Pipestone, Lyon, Lincoln, Murray, Cottonwood, Nobles and Jackson.

Philadelphia

Rush Memorial.—A plan to preserve the homestead of Berry Rush at Byberry as a medical museum in memory of the early Philadelphia surgeon has been advanced by Mrs. C. D. Joyce, owner of the property. The old house is still standing and is near the city farms at Byberry.

Laboratory Chartered.—Judge Staake has chartered the dermatologic research laboratories which were formed in November, 1912, for the prime purpose of discovering psoriasis. The membership of the associates working in this laboratory includes Dr. J. Chamberg, Dr. F. J. Colmer, Dr. David Riesman and Dr. Albert D. Ferguson.

Officers Elected.—At the stated meeting of the Philadelphia Genito-Urinary Society, February 24, the following officers were elected for the ensuing year: president, Dr. Benjamin A. Thomas; vice president, Dr. A. Haines Lippincott; secretary-treasurer, Dr. William H. MacKinney, and chairman executive committee, Dr. Charles S. Hirsch.

City Physicians' Strike Off.—Forty-seven of the city's assistant school inspectors, who demanded an increase in salary from $600 to $1,000 a year, have withdrawn their demands. There are 220,000 schoolchildren in the city, and the work of these physicians consists not alone in protecting children from disease, but also in improving the health of those who are poorly nourished and in continuing the education of the crippled and tuberculous. A clinic is maintained for the examination of those mentally deficient. Truant children are visited to determine their physical fitness. The report of the work shows that sixty-four physicians and forty-one nurses last year made 147,631 examinations and discovered 143,172 physical defects and diseases.

Personal.—Joseph Sailer, Lieutenant-Colonel, M. C., U. S. Army, and Benjamin F. Baer, Charles F. Nassau, and Albert P. Francine, Majors, M. C., U. S. Army, have returned to this country.——Dr. Jacob S. Cohen, for many years professor of electrotherapeutics in the Jefferson Medical College, was 81 years old, February 27.——Lieut. Andrew Knox, M. R. C., has received the English military cross for gallantry in the field under heavy machine gun fire.——Dr. S. Leon Gans of Philadelphia, surgeon in the Spanish War, and a captain in the Army, has been named chief of the genito-urinary dispensaries of the state department of health.——Dr. Samuel Friedenberg has been appointed assistant medical inspector of the bureau of health.——Drs. Howard S. Mace, D. J. Gallaher and M. Chapiero have been appointed assistant medical school inspectors.——Dr. William Campbell Posey, for twenty-five years attending physician at Wills Hospital, has been elected as consulting physician to the hospital.——Dr. Thomas E. Conard has been appointed acting attending surgeon to the institution.——Dr. Luther C. Peter has been elected professor of ophthalmology in the Graduate School of the University of Pennsylvania.——Dr. William Williams Keen had conferred on him the honorary degree of Doctor of Laws by the University of Pennsylvania, university day. In conferring the degree, Provost Smith paid the following tribute to Dr. Keen:

> "William Williams Keen, voluminous writer on medical subjects, especially surgery, in which you have an international reputation.
>
> "Corresponding member of learned societies in England, Scotland, Belgium, France and Italy.
>
> "Honored at home and abroad by ancient universities with their highest degrees. Author of meritorious historical documents. Active participant in all social movements of an uplifting nature, sturdy patriot. Only commissioned officer in the present war who was a comsioned officer during the Civil War. Beloved teacher, honored citizen, I confer upon you the degree of doctor of laws.

RHODE ISLAND

Program of Public Health Work.—Gov. R. Livingston Beekmann has recently given public health work in Rhode Island a great impetus by becoming personally responsible for a large program. In October he called Dr. Lydia Allen DeVilbiss, Topeka, director of the division of child hygiene, Kansas State Board of Health, to make a study of the health conditions as related to the children of Rhode Island, and to formulate a program for child welfare. As a result of this investigation and report, bills have been introduced into the legislature creating a division of child hygiene and a division of vital statistics in the state board of health; a director of health and physical training of the state normal school who shall be ex-officio state director of medical inspection in the schools; and removing some of the existing disabilities of the school attendance law and strengthening the present child labor legislation.

VIRGINIA

Personal.—The residence and office of Dr. Robert A. Warren, Hot Springs, including the Midway Inn, which was owned by the family, were destroyed by fire, February 22, with a loss of $50,000.——Dr. W. D. Sydnor, Hamilton, is under treatment in the Loudoun Hospital awaiting operation for chronic appendicitis.

CANADA

Hospital News.—Twenty-three of the leading physicians of Calgary, Alta., have issued a statement giving their hearty approval to the municipal hospitals scheme of that province. They have not been opposed to these hospitals but opposed to political capital being made out of the movement.——A tuberculosis hospital is to be built at Bowness, Alta. The cost is to be $400,000, of which the province will bear $200,000 and the dominion government $200,000.

Osteopathy Still Banned in Quebec.—The osteopaths have not been successful in getting the bill for license to practice in that province passed by the public bills committee of the legislature, but state that they will keep on renewing the fight each year.

Tuberculosis a Serious Menace in Quebec.—The Quebec government has studied the question of tuberculosis in that province and has found that 3,000 die annually. The contract between the provincial and federal governments to provide for the extension of the work of caring for the tuberculous at Ste. Agathe has been ratified by the legislature, and the institution will be used for the next five years solely for soldiers with tuberculosis. The sanatorium was established in 1911 with seventy beds, and has treated 795 patients. It will be extended to 271 beds.

Personal.—Major Frederick N. G. Starr has returned from overseas to Toronto.——Col. Herbert A. Bruce is returning to Toronto from overseas after several years' service, and is bringing with him an English bride.——Capt. Charles G. Cox, Humboldt, Sask., has been permanently attached to the local board of pension commissioners as medical examiner.——Dr. Andrew Croll, who has been overseas some years, has resumed practice in Saskatoon. Latterly he has been chief surgeon at Camp Hill Military Hospital, Halifax, N. S.——The Order of Companions of St. Michael and St. George has been conferred on the following members of the Canadian Army Medical Corps: Cols. Hugh Chisholm; Spurgeon Campbell, Winnipeg, Mann.; John Kidd; William Simpson, and Robert P. Wright, Quebec; and the order of Commanders of the Order of the British Empire on Cols. George D. Farmer, Ancaster, Ont., and John Stewart, Halifax, N. S.——Dr. Mowat has reached his home in Ottawa, Ont., having returned from overseas where he had been for some time a prisoner in Germany.——Dr. Thomas A. Carson, Orangeville, Ont., who has been in France, has returned and been appointed on the pension board, Ottawa.

GENERAL

Bequests and Donations.—The following bequests and donations have recently been announced:

Marquette Medical School Dispensary, $133,000 as an endowment by the family of Patrick Cudahy.

Johns Hopkins Hospital, Baltimore, $400,000 for the erection of a building to serve as a women's clinic by an anonymous donor.

Johns Hopkins University, Baltimore, the "Tudor and Stewart Club" in memory of Revere Osler, endowed by Sir William and Lady Osler.

Personal.—At the French General Headquarters, January 10, the Croix de Guerre with gold star was conferred on Percy L. Jones, Col., M. C., U. S. Army, chief of the American Sanitary Section of the French army.——Major-General and Mrs. Merritte W. Ireland entertained at dinner thirty guests recently, in honor of Victor C. Vaughan, Col., M. C., U. S. Army, Ann Arbor, Mich., and Mrs. Vaughan.

Appropriations for Hospitals.—February 21, the following appropriations were made for hospitals for returning soldiers and sailors: for the establishment of a hospital in Cook County (Speedway Hospital), $3,000,000; for the establishment of a hospital at Dawson Springs, Ky., $1,500,000; for the establishment of a hospital, at Norfolk, Va., $900,000; for the establishment of a hospital in the District of Columbia, $500,000; for improvements in operations on the hospital at Stapleton, Staten Island, N. Y., $190,000.

Tri-State Election.—At the annual meeting of the Tri-State Medical Association of Virginia and the Carolinas, held at Richmond, Va., February 19, under the presidency of Robert S. Cathcart, Major, M. C., U. S. Army, Charleston, S. C., the following officers were elected: president, Dr. Robert C. Bryan, Richmond; vice presidents, Drs. Clifton M. Miller, Richmond; Andrew J. Crowell, Charlotte, N. C., and Augustus R. Taft, Charleston, S. C., and secretary-treasurer, Dr. Rolfe E. Hughes, Laurens, S. C. The association will hold its next meeting at Winston-Salem, N. C.

Joint Influenza Committee.—It was announced, February 20, that a joint influenza committee has been created by the Surgeon-Generals of the Public Health Service, the Army and the Navy, and the director of the census, to study the epidemic of influenza and to make comparable the influenza data gathered by the government departments. The committee consists of Dr. William H. Davis, Washington, D. C., chairman, and Mr. C. H. Sloane of the Census Bureau; Dr.

Wade H. Frost, Washington, D. C., and Mr. Edward Sydenstricker, of the Public Health Service; Col. Deane C. Howard, Col. Frederick F. Russell and Lieut.-Col. Albert G. Love of the Army, and Lieut.-Com. Joseph R. Phelps and Surg. Carroll Fox of the Navy.

Aspirin and Espionage.—In an address in Philadelphia, March 1, according to the Philadelphia *Public Ledger*, Mr. A. Mitchell Palmer, made some "startling disclosures of the extent to which German capital operated in this country with purposes hostile to America." The *Ledger* says in part:

> Mr. Palmer told how when the Bayer Aspirin Company was seized in New York twenty-three trunks were found in the cellar of the building. Officials of the company explained that these trunks contained clothing belonging to employes and when they were opened they were found to contain the papers of almost the entire workings of the *Bernstorff* system of espionage.

Public Health Education Campaign.—A nation-wide campaign for public health education is one of the first of the peace time activities to be undertaken by the Red Cross, and plans for this are well under way. Realizing that the Chautauqua itineraries offered unusual opportunities to reach communities most in need of health work, the Red Cross Department of Nursing is assigning between thirty and forty of its most able nurses, who have just returned from overseas, to lecture on the principal Chautauqua circuits throughout the country. The lectures are to start about June 1. In each instance the lecture will be followed by a squad of other nurses and Red Cross workers, who will conduct a health exhibit and give practical demonstrations.

Influenza.—According to *Public Health Reports*, February 21, with local variations the number of cases of influenza reported has declined since about the middle of January in all parts of the country from which reports have been received. Reports to the service for the week ended February 15 indicate a general decline in the number of cases. As compared with the previous week, fewer cases were reported in Alabama, California, Connecticut, Florida, Illinois, Iowa, Kansas, Louisiana, Maine, New Jersey, North Carolina, Ohio, Oklahoma and Virginia. Arkansas and Vermont reported increases, but the number of cases was not large. Reports from the extracantonment zones indicate a slightly smaller number of cases than for the previous week.

Country Districted for Social Hygiene Board.—For purposes of administration, the Interdepartmental Social Hygiene Board has established districts as follows, each district being in immediate charge of a supervisor:

District 1.—Maine, New Hampshire, Vermont, Massachusetts, Connecticut, Rhode Island.
District 2.—New York, New Jersey, Pennsylvania, Delaware.
District 3.—Maryland, District of Columbia, Virginia, West Virginia.
District 4.—Tennessee (Eastern), North Carolina, South Carolina, Georgia, Florida (Eastern).
District 5.—Florida (Western), Alabama, Mississippi, Louisiana, Tennessee (Western), Arkansas.
District 6.—Texas, Oklahoma, New Mexico.
District 7.—Arizona, California, Oregon, Washington.
District 8.—Utah, Nevada, Idaho, Montana, Colorado, Wyoming.
District 9.—North Dakota, South Dakota, Nebraska, Kansas, Missouri, Illinois, Iowa, Wisconsin, Minnesota.
District 10.—Michigan, Indiana, Ohio, Kentucky.

Welcome to the Spanish Edition of The Journal.—The *Gaceta Medica de Caracas* of Nov. 30, 1918, reproduces the official announcement of the publication of the Spanish edition of THE JOURNAL, and comments as follows: "We publish the letter which follows in order to let our colleagues of Venezuela know of the praiseworthy undertaking of the American Medical Association to issue an edition in Spanish of their interesting periodical, which under a thousand titles will be of true usefulness by its extensive, selected and varied reading matter. We hope that the Venezuela medical profession will give it decided support." Elsewhere in the same issue the *Gaceta* publishes an address by Dr. O. Montoro at a meeting of the Association of the Medical Press of Cuba. His subject was professional ethics. He emphasized that the press in general should feel called to improve customs in vogue if by doing so the progress and the happiness of the country would be promoted. "The medical press in particular has the obligation to watch out for the purity and the dignity of the profession, hundredfold worthier and nobler than those who are striving to corrupt it. We all of us know the organ of the American Medical Association. THE JOURNAL has been carrying on for a long time a campaign from which it has not been diverted by the powerful interests which attack it or by any influences, but continues its campaign to improve the professional morality among American physicians and sweep the market clear of many proprietaries which, as the least of the harm they do, defraud the patient. No one conscious of his duty can fail to realize the great influence which these campaigns have had on the moralization of a people and of a social class. And all this the American medical press realizes by means of its powerful Association and its admirable and well known organ, THE JOURNAL."

New Child Labor Law.—The new child labor law, passed by Congress, *in effect prohibits the* employment of children under 14 in factories, and of children under 16 in mines and quarries, insures a maximum eight-hour day, and prohibits night work for children between 14 and 16 employed in factories. As pointed out by the Children's Bureau, however, the number of children employed in the designated occupations is comparatively small, and even after the law is in force young children will be able to work at some time, in some occupations, in practically every state in the Union, and in many states boys and girls will be permitted to work long hours. The children not covered and protected by the Child Labor Law will have only such protection as is afforded by the varying laws of the states in which they live. Thus, while California, Michigan, South Dakota, Texas, Montana and Ohio fix the minimum age higher than 14, all except Ohio have exemptions from the law. New Mexico, Utah and Wyoming have no minimum age law except for children in certain dangerous or injurious occupations. North Carolina and Mississippi have a minimum age restriction less than 14, and many of the thirty-eight states, including the District of Columbia, have 14 as the minimum age, but grant exemptions allowing children under 14 to work in certain occupations, or during vacation, out of school hours, in case of poverty, or under other specified conditions. Seventeen states permit the employment of children under 16 for more than eight hours a day and forty-eight hours a week; two states place no limit on hours of work; thirty which have an eight-hour day do not cover all occupations and have certain exemptions; seven states do not forbid night work, while others prohibit it in certain occupations. The bureau calls attention to the fact that most states fail to protect children in agriculture and domestic service.

Board for Ophthalmic Examinations.—The American Board for Ophthalmic Examinations will hold its next examination at the Wills Eye Hospital, *Philadelphia, June 6 and* 7, 1919. This examination will be the fifth to be conducted by the board, which is composed of representatives of the American Ophthalmological Society, the Section on Ophthalmology of the American Medical Association, and the Academy of Ophthalmology and Oto-Laryngology. For a certificate of this board, the examination in ophthalmology consists of case records; written examination, and clinical laboratory and oral examinations, or so much thereof as may be judged necessary. Candidates in ophthalmology are required to submit twenty-five complete case records, of which not more than ten should be descriptive of operations. These records should be of cases of ocular diseases and defects of varied character, including errors of refraction or muscle balance, and external ocular diseases or diseases of the uveal tract or retina, or of the optic nerve, or glaucoma. The reports should show especially the reasons for the diagnosis, and for the operative treatment and the technic of operations in operative cases. The written examination will test the candidate's knowledge of the underlying principles of the science of ophthalmology, including anatomy, embryology, physiology, physiologic optics, pathology, relations of the eye to the other organs and diseases of the body. The oral examination will include: the external examination of the eye; ophthalmoscopy (candidates are requested to bring their own ophthalmoscopes); measurements of errors of refraction; testing of the ocular movements and fields of vision; relations of ocular conditions to diseases of other parts of the body and their treatment, and laboratory examination in histology, pathology and bacteriology of the eye. Further information may be had on request from the secretary, Dr. William H. Wilder, 122 South Michigan Avenue, Chicago.

FOREIGN

Deaths from Plague.—February 18, it was reported from Buenos Aires that in the *seven* preceding days there had been three deaths from bubonic plague.

Influenza Increases.—During February there was reported to have been a great increase in cases of influenza in Paris.

For the first three weeks in February, deaths from this disease were 284, 370 and 550.

War Hospital Closed.—The American Red Cross Hospital at Neuilly, organized in the first week of September, 1914, by a prominent American, and one of the most conspicuous establishments in caring for the wounded during the war, was closed, February 6.

Mission to Roumania Leaves Constantinople.—The American Red Cross Mission, which is headed by Dr. H. Gideon Wells, Chicago, consisting of forty-nine members, left Constantinople for Constanza, February 16, with 4,000 tons of relief supplies. These supplies were supplementing three boatloads of foodstuffs already sent to Roumania by the American Food Administration. The American Red Cross has 10,000 tons of additional foodstuffs, medicine and clothing on the way to Roumania.

Typhus Fever in Moscow.—Advices to the state department of Helsingfors state that twenty French physicians, twelve British, seven Belgian, five Italians and one American comprise a party of war relief workers that has returned from Moscow to Stockholm. They reported that there are 1,000 cases of typhus fever in Moscow, weekly, that hospitals are unable to take care of patients, many having to lie in halls without beds, and that the personnel of hospitals are largely incapacitated because of illness.

Proposed Merging of Danish Medical Societies.—Professor Rovsing of the University of Copenhagen, editor in chief of the *Hospitalstidende*, has offered this weekly as the organ of the united medical societies, urging that the medical societies of Denmark merge to form a single association. The Copenhagen Medical Society held a special meeting in November at which the plan was adopted, with forty-two ayes to two noes, that the Danish medical societies merge to form one Danish medical society, and to select the *Hospitalstidende* as its organ. The Alm. Danske Lægeforening has its own journal, the *Ugeskrift for Læger*. Both of these weeklies are regularly indexed in the Current Literature Department.

Red Cross Hospital Closed.—The American wounded in England are being evacuated to the United States so rapidly that it has been possible to close a number of the hospitals. American Red Cross Hospital No. 23 (St. Katherine's Lodge) has already been closed, and among the others that will soon be closed are American Red Cross Convalescent Hospital for Officers, at Lingfield Surrey, American Red Cross Hospital No. 21 at Paignton, North Devon, and army hospitals built by the American Red Cross at Romsey, Hursley and larger base hospitals at Portsmouth, Dartmouth and Tottenham. Sarisbury Court, Southampton, and two military hospitals at Liverpool will be the only American hospitals in Great Britain to be conducted through the winter.

Deaths in the Profession Abroad.—**Dr. Alois Epstein,** professor of children's diseases at the German University of Prague and chief of the children's clinic and foundlings' asylum.——**Dr. L. Stieda,** formerly professor of anatomy in turn at the universities of Dorpat, Königsberg and Giessen, aged 81.——**Dr. W. Anton,** professor of otorhinology at the German University of Prague, aged 58.——**Dr. Galcerán Granés,** professor of nervous and mental diseases at the University of Barcelona, and member of the editorial staff of the *Gaceta Medica Catalana*.——**Dr. S. M. Palomino,** subdelegado de medicina at Madrid, and editor of the *Monitor Sanitario*.——**Dr. V. Cervello,** professor of materia medica at the University of Palermo, noted for his work on the paraldehyds, adonis and iron, and founder of the *Archivio di Farmacologia e Terapeutica,* aged 64.

SOUTH AND CENTRAL AMERICA AND WEST INDIES

New Chief of Public Health Service in Venezuela.—Dr. L. G. Chacin Itriago of Caracas has recently been appointed director of the Oficina de Sanidad Nacional of Venezuela.

Death of Professor Pereira.—Dr. Miguel Pereira, professor of clinical medicine at the University of Rio de Janeiro; in 1910 president of the Academia Nacional de Medicina; leader in the Saneamento do Brazil movement, and author of numerous works on internal pathology and clinical medicine, died recently after a long illness, aged 47. Nearly the whole issue of the *Brazil Medico* for December 28 is devoted to obituary notices and tributes to Dr. Pereira spoken in the senate, the chamber of deputies and at the inauguration of the new building of the local medical society, which was deprived of all festival character by the loss of this prominent member.

MEXICO LETTER

MEXICO CITY, Feb. 16, 1919.

Interchange of Professors and Students

The Associated Press has given out word that the arrangements have been concluded for the establishment of the interchange of professors and students between the University of Washington and the University of Mexico. Special attention is to be paid to the study of the language, history and evolution of the two countries for the purpose of stimulating mutual acquaintance and cultivating friendly relations between the two nations.

Effects of Alcohol

On a single day recently sixteen persons were sent to the public insane asylum, the Manicomio General, affected with mental derangement of different kinds, all of which were attributed to the abuse of alcohol. The horrifying feature of the event was that all of them were youths, none having reached the age of majority, and the youngest was only 12 years old.

Personal

Sr. E. L. Vallejo, a veterinary physician, has recently been elected a member of the Sociedad Mexicana de Geografia y Estadistica, one of the oldest scientific bodies of the country. His address on being received a member was entitled, "Historical and Geographic Data on Anthrax and Its Preventive Vaccine in the Republic of Mexico."

Prosecution of a Quack

In the city of Guadalajara, Jalisco, a man has been apprehended—and it is the first time this has occurred, to my knowledge—for practicing medicine without having conformed to the legal requirements. The name of the accused is Felipe Ochoa. A petition was presented to the legislature of the state of San Luis, signed by a number of professional men, urging the passage of a law to regulate the practice of the liberal professions, and to exclude the unqualified from practice. The legislature to date has not taken any steps to remedy the grave evil of allowing charlatans to practice unmolested, an evil which affects nearly the entire country.

The Wassermann Reaction

For some unexplained reason, the aim and purpose have been missed of the new ordinance compelling the production of a certificate of health as an indispensable prerequisite to marriage, the certificate to be based on the negative findings of the Wassermann test. At present, the candidate has only to present a certificate based solely on the clinical findings, which is far from being an efficient guarantee of safety. Some of the sensational periodicals undertook a campaign against this beneficent ordinance and published articles inspired by physicians either unscrupulous or behind the times in which they sought to convince the general public that the Wassermann reaction has absolutely no diagnostic value.

LONDON LETTER

LONDON, Feb. 5, 1919.

Treatment of Disabled Soldiers

A scheme for the treatment of disabled soldiers has been drawn up by Sir John Collie, director of the medical service to the ministry of pensions. All the types of cases have already been dealt with at an earlier stage by the army medical service, which has equipped and staffed special hospitals and originated special teams of research workers. At the present rate of demobilization, ample room exists in the military hospitals for pensioners. Consequently the ministry of pensions will not embark on a scheme of separate hospitals—which, indeed, it could not staff at this moment. It has been the policy of the ministry of pensions to work as a civil rather than as a military organization. The discharged disabled soldier resents military discipline, and cannot feel the same confidence in a body presided over by military men as in a body presided over by civilians. To overcome this difficulty it is proposed to appoint a liaison officer to the pensions ministry to work between the director-general of the army medical services and the director of medical services of the ministry of pensions. As the military hospitals are demobilized they can be taken over by the ministry of pensions. But there must be continuity of treatment. The war has provided a medicine and surgery of its own, and physicians in large numbers have been trained in new methods. Orthopedic methods are now universally looked on as necessary to the proper handling of disablement.

The army possesses splendidly equipped orthopedic hospitals and workshops, and practically controls the physicians and nurses qualified to undertake this work. These physicians and nurses should become in time the staff of the ministry of pensions so that the work can be carried on into civil life. In the same way diseases like malaria, dysentery and trench fever have been specially provided for, specially studied and specially controlled. Teams of workers have learned how to recognize these diseases, how to prevent their spread, and how to treat them. The civilian medical profession as a whole knows little or nothing about them. These teams and their special hospitals must gradually be taken over as going concerns by the ministry, as much in the interests of the civil population—to prevent the spread of infection—as of the men themselves.

The Treatment of Dysentery in the Army

There are a large number of cases of dysentery in the military hospitals in this country contracted on service in the eastern theaters of war. For their treatment and the prevention of the spread of the disease to the civilian population an important army council instruction has just been issued. It provides in the fullest possible way for the care of the dysentery cases. It orders that "all patients suffering or convalescent from dysentery will, if fit to travel, be sent to one of the selected dysentery hospitals, where they will be examined, treated, and disposed of." These special hospitals must have on their staffs a bacteriologist and a protozoologist, and the cases are to be in charge of medical officers specially selected for their experience in or aptitude for the work, and as few changes as possible are to be made in these appointments. On admission of a patient to a selected hospital, steps will be taken at once to verify the diagnosis of dysentery and to exclude the possibility of the man being a carrier of the disease. A standing medical board is to be appointed at the Central Dysentery Hospital (Addington Park Military Hospital), one of the members of which shall belong to the laboratory staff of the hospital. The duty of this board is to make periodic examinations of all carriers and of such severe or relapsing cases as may have been transferred to the central hospital from the other special hospitals. Every "healthy" or "uncured" amebic carrier who elects to be discharged while still a carrier will be required to sign a paper stating that his condition has been explained to him and that he has been offered and has refused a course of specific treatment. The high percentage of recoveries after specific treatment properly administered will be explained to each man. On the discharge from any hospital of an uncured or chronic case of dysentery (amebic or bacillary) or any bacillary carrier, a notification shall be sent on or shortly before the date of discharge to the medical officer of the local government board. This note shall give the man's name, his age, address, date and place of original attack of dysentery, and history of relapses, summary of bacillary and protozoologic findings, with dates and note as to emetin or other specific treatment received.

German Brutality to a Prisoner

A coroner's inquest into the death of Private Robert William Varder of the Northamptonshire Regiment, a repatriated prisoner from Germany, exemplifies the abominable inhuman treatment to which many of our soldiers have been subjected. The father of the deceased gave evidence that his son joined the army in September, 1914, when under age, being 5 feet 11 inches in height and weighing over 11 stone (more than 154 pounds). He was an athlete. When the witness saw him in the Fulham Hospital, January 2, after returning from Germany, he was so emaciated and completely changed that if the sister had not pointed him out he would not have known him. His son had not received any of the many parcels that had been sent to him. He had had no medical treatment, and the only food he had was when they went out and gathered potato peelings, and worm-eaten cabbage leaves, which had been thrown away. No other food was provided for him. The coroner said that Varder had given this account to the army surgeons who attended him in this country: He was taken prisoner by the Germans last April, and was released about the date of the armistice. While at work in a prisoners' camp behind the German line in Belgium, he failed to interpret an order of a German sergeant, who then struck him a fatal blow with the butt end of a rifle. He was very emaciated and was not allowed to go sick. A large abscess formed as the result of the blow. Blood poisoning set in and caused his death. The coroner produced photographs of Varder taken before his capture and since his return from Germany. Formerly he weighed 12 stone (168 pounds), and when repatriated only 4 stone (56 pounds), being practically skin and bone. Capt. A. Leakey, R. A. M. C., of the Fulham General Hospital, gave evidence that when admitted Varder was emaciated and feeble. He had a large abscess on the thigh, which was consistent with his having received a blow. Varder had told him that the abscess was opened without an anesthetic, and a pint and a half of pus removed. The only attention he had afterward was from a soldier. In reply to the coroner's question, Would the operation be a painful process? he said, "Extremely, and from a surgical point of view barbarous." When Varder arrived in England the wound was 10 by 3 inches and was still open. He was too ill for an operation. There would have been nothing serious in the injury if he had been properly treated. The jury returned a verdict that death was due to blood poisoning, following a blow with the butt of a rifle inflicted by a German guard, and that death was accelerated by gross neglect on the part of the German military authorities in not affording him proper nourishment and treatment.

Medical Graduate Course in London

The Interallied Fellowship of Medicine has arranged with the medical schools in London for "an emergency postgraduate" course of three months for qualified physicians belonging to the medical services of the Royal Navy, Army, Air Force, the overseas contingent, the United States and Allies. Officers joining the course will be admitted to the general practice of the hospitals, including the clinical work of the wards and outpatient departments, clinical lectures and demonstrations, postmortem demonstrations and laboratory work. Tickets for the whole course, or for one or two months, are issued at the rate of $17 for each month. They can be obtained from the secretary of the fellowship, 1 Wimpole Street, London, W. I.

PARIS LETTER

Paris, Feb. 6, 1919.

Treatment of Syphilis in the Army During the War

This subject was discussed at a recent meeting of the Société française de dermatologie et de syphiligraphie. Dr. Leredde, chief of the laboratory of the hôpital Saint-Louis, considers the methods of treatment of syphilis advocated by the Service de Santé militaire as being inefficacious. He believes that of the 200,000 to 300,000 persons who contracted syphilis during the war, three fourths remain actively syphilitic and spread the disease. He has discovered many cases of undetected syphilitic chancres, and a large number of persons who even after treatment had a positive Wassermann and who were capable of transmitting the disease.

Dr. Clément Simon protested against exaggerating the figures. In 1916, the army authorities reported 9,000 cases of syphilitic chancres. Multiplying these figures by five gives a total of 45,000 cases reported during the war. Adding to this number the unrecognized and not reported cases, it is safe to say that 90,000 cases may be considered the maximum figure.

Dr. Brocq, who with Dr. Thibierge, was consulted by the undersecretary of state for the Service de Santé militaire in 1915 as to the method of treatment of syphilis to be adopted, advised that it was not so important to give a thorough course of treatment as it was to "blanch" the syphilitics rapidly. Therefore, physicians were advised to use arsenic compounds, such as arsphenamin.

Dr. G. Thibierge was of the opinion that if any syphilitics remained undetected, it was due to the fact that the army surgeons did not make the regulation medical inspections systematically. A patient with a syphilitic chancre should not remain hospitalized more than six weeks. In the American army persons with chancres are not hospitalized. He believes that it was wrong, at the beginning of the war, to hospitalize the gonorrheics.

Health of Lille During the War

At the last meeting of the Académie de médecine, Dr. Calmette, director of the Institut Pasteur de Lille, denounced the acts of cruelty committed by the German army and nation on the inhabitants of Lille. He cited most convincing figures in support of his remarks. In 1915, the mortality rate of Lille was 27 per thousand inhabitants; in 1916 it was 29 per thousand; in 1917, 30 per thousand, and in 1918 it was 41.55 per thousand. The principal causes of this high mortality were tuberculosis, dysentery, scurvy and heart disease. All diseases caused or aggravated by insufficient food rations also increased the mortality rate. Nor is this the only result of these acts. Young boys and girls have not developed normally; hence immediate steps should be taken to remedy these conditions. Calmette addressed an urgent appeal to the authorities to adopt urgent remedial measures at once, distributing substantial food to the children and the young, giving constant medical care, fighting tuberculosis in every possible way, both by notification and by treatment.

Transport of Wounded by Aeroplane

It is interesting to report the first trial of the plan of transporting the wounded by aeroplane. General Paeymirau was recently wounded on the Moroccan front, a shell fragment striking him in the region of the heart. He was transported by aeroplane to Bou-Denib in eastern Morocco on the Algerian front, thus avoiding the shaking to which automobile transportation would have subjected him.

Closing the Netherlands Hospital in Paris

A farewell dinner was tendered to Dr. Van Tienhoven, medical chief of the Netherlands Hospital of Pré-Catelan, and to all his assistants, as well as to the personnel of Auxiliary Hospital No. 77, established in the early months of the war by the Hamburger brothers. In the course of remarks made on that occasion, M. Loudon, formerly minister of foreign affairs for Holland, called attention to the fact that this hospital had cared for 1,658 wounded, with 121,066 hospital days, and that Auxiliary Hospital No. 77 had cared for 1,024 wounded with 46,304 hospital days.

War Welfare Work and Peace Reorganization

The representatives of most of the war welfare agencies recently met at the Musée social under the presidency of M. Leon Bourgeois in order to determine on the activities to be carried on now by these organizations, and to effect a reorganization for that purpose. War victims should receive the aid to which they are entitled and they should never be made to feel that this is a charity or in the nature of alms. A commission was appointed to devise ways and means to make this plan of cooperative action effective.

Society of Friends of the Paris Medical School

A society, called the Amis de la Faculté de médecine de l'Université de Paris, has been formed for the purpose of improving the methods of teaching in the University of Paris, the study facilities for the students, the scientific research laboratories, to favor the expansion of French medicine among foreigners, and to contribute to the advancement of medical science.

Students Celebrate Victory

January 26 an imposing demonstration was held in the Sorbonne by the Association générale des étudiants de Paris in celebration of victory. M. Paul Deschanel, president of the chamber of deputies, presided, assisted by M. L. Lafferre, minister of public instruction. The president of France and Mme Poincaré were present, likewise Dr. Louis Mourier, undersecretary of state for the Service de Santé militaire, and Dr. Roger, dean of the Paris faculty of medicine.

Closing the Canadian Hospital at Saint Cloud

On the occasion of the closing of this hospital a banquet was given and a reunion was held at which Dr. Louis Mourier presided, and which was attended by the Canadian delegates to the Peace Conference and the principal notables of the French and the English armies. Dr. Mourier thanked the Canadian doctors for their cooperation and their devotion to the French soldiers. More than 5,000 severely wounded soldiers have been cared for in this hospital as well as a large number of medical patients.

Medical Society of the Grand Duchy of Luxembourg

The Société des Sciences médicales of the Grand Duchy of Luxembourg on Jan. 12, 1919, voted unanimously to go on record as approving the medical studies and medical standards of France. They extended their felicitations to the French medical corps and to their colleagues of Alsace and Lorraine who are natives of the Luxembourg frontier.

Personal

The following persons have been appointed members of the Commission supérieure consultative de santé: Professor Letulle, Paris; Dr. Lagrange, Bordeaux; Dr. Léon Bernard, Paris; Dr. Abadie, Bordeaux; Dr. Crouzon, Paris; Dr. Levassort, secretary-general of the Association des médecins de France, and Dr. F.-V. Helme.

Deaths

Dr. Sabatié, chief physician of the complementary hospital of the Polytechnic School, is dead.

Dr. Henri Chéron, former chief of the obstetric clinic of the Paris medical faculty, died at the age of 50. He was born in Paris, the son of a gynecologist of repute, and had devoted himself particularly to roentgen and radium therapy. He was the founder of the Oeuvre philanthropique du radium, and was charged with the work of giving such treatment to the sick poor. He represented the radiotherapists at numerous French and international congresses.

Dr. H. Bernheim, honorary professor on the Nancy medical faculty, died in Paris. He was the author of a well known work on hypnotism besides many purely medical studies.

Raising the Birth Rate

The senate has concluded its discussion of a proposed law to combat depopulation by the adoption of appropriate measures tending to increase the birth rate. One of the provisions in this law bears on professional secrecy. It reads as follows: Physicians, midwives and pharmacists, who are called as witness in a prosecution for abortion, may, without laying themselves liable to article 378 of the Penal Code (which provides for imprisonment of from one month to six months and a fine of from 100 to 500 francs for revealing secrets which may have been confided to them either professionally or as agents of the state), testify to the facts in the case on trial, providing that they will not bring into the case any person, other than the accused, toward whom they are obliged to maintain professional secrecy. An added amendment exempts from punishment any woman who will make known the abortive maneuvers practiced on her, and who will cause the arrest of the person who performed the abortion. The senate also accepted an amendment providing for imprisonment of from six months to one year of any midwife who has in her possession or who has placed in the home of some one else the instruments used to perform abortion. The senate has adopted this law, but it has not yet been examined by the chamber of deputies.

Health Measures for Liberated Regions

The minister of the interior has appointed a commission, of which Dr. Louis Mourier is the head, to study and apply measures to conserve the health of the population of the liberated regions. Among the members of this commission are: Professors Chantemesse, Marfan, Netter and Widal, members of the Académie de médecine; Drs. Léon Bernard, Méry, Jules Renault and Sergent, physicians of the Paris hospitals; Dr. Roux, director of the Institut Pasteur de Paris, and Dr. Calmette, director of the Institut Pasteur de Lille.

Military Hydrotherapeutic Hospitals

Dr. Molinéry has suggested to the Société de médecine de Paris that the military hydrotherapeutic hospitals be reorganized, providing for laboratory, surgical and physiotherapeutic departments. He also suggested the appointment of a medical commission, consisting of outside physicians, by whom patients will be examined so that the proper hydrotherapeutic treatment can be outlined.

Marriages

William Howard Michael, Lieut.-Com., P. A. Surg., U. S. Navy, Washington, D. C., to Mlle. Marcelle Mortier of Neuf Chateau, Vosges, France, at Rouceaux, France, in January.

Bennet Roland Parker, Lieut., M. C., U. S. Army, Chicago, on duty at Nantes, France, to Miss Edith Helene Matthies, at Nantes, January 27.

George Elkington Moore, Asst. Surg., Lieut. (j. g.), U. S. N. R. F., Madison, Wis., to Miss Louise M. Kroll of Brooklyn, February 12.

John Martin Whalen, Lieut., M. C., U. S. Navy, Grand Rapids, Mich., to Miss Arline Turpell, at Washington, D. C., February 4.

George Francis Brackett to Miss Elizabeth Evelyn Cain, both of San Francisco, in Sacramento, Calif., February 15.

Wallace Krugler to Miss Blanche Edith Ehrlich, both of New York City, February 11.

Edward Benedict Malloy to Miss Sadie Steinmetz, both of Akron, Ohio, February 25.

Deaths

James Tyson ⊕ Philadelphia; University of Pennsylvania, Philadelphia, 1863; aged 77; professor of pathology and morbid anatomy in his alma mater from 1876 to 1889; secretary of the medical faculty from 1877 to 1888, and dean from 1888 to 1892; professor of practice of medicine from 1899 to 1910; and since that time emeritus professor; president of the Medical Society of the State of Pennsylvania in 1911; president of the Association of American Physicians in 1907-1908; and of the College of Physicians of Philadelphia from 1907 to 1910; author of numerous monographs and textbooks, the most notable of which are those on "Practical Examination of Urine," "Physical Diagnosis," and "Textbook of Practice of Medicine"; at one time assistant editor of the *Philadelphia Medical Times;* pathologist to the Philadelphia General Hospital from 1870 to 1872; visiting physician since 1872; and president of the medical board from 1886 to 1890; consulting physician to the Kensington Hospital for Women; one of the incorporators, a trustee and chairman of the executive committee of the Rush Hospital for Consumption and Allied Diseases; acting assistant surgeon, U. S. Army, during the Civil War; died at his home, February 21.

Clarence Ewen ⊕ **Major, M. C., U. S. Army** (retired), Washington, D. C.; Bellevue Hospital Medical College, 1862; aged 75; assistant surgeon of the 53d New York State Volunteers in 1862; assistant surgeon of the 102d United States Volunteers in 1862 and 1863; acting assistant surgeon, United States Army, 1864; assistant surgeon of the 29th United States colored troops in 1864 and 1865; acting assistant surgeon, United States Army, in 1868; who entered the regular establishment as lieutenant and assistant surgeon in 1868, was made captain in 1869, promoted to major in 1889, and was retired at his own request after more than thirty years' service, Jan. 26, 1897; died at his home, January 6.

James Madison Gora Carter ⊕ Los Angeles; Northwestern University Medical School, Chicago, 1880; aged 75; formerly of Chicago and Waukegan, Ill.; president of the Illinois State Medical Society in 1897 and 1898; a veteran of the Civil War, and a prisoner in Libby prison; professor of pathology and hygiene from 1891 to 1895; professor of clinical and preventive medicine from 1895 to 1899, and professor emeritus since 1900, in the College of Physicians and Surgeons, Chicago; a member of the American Academy of Political and Social Science, and the American Historical Association; died at his home in Los Angeles, March 3.

Leonard Michael Kalaher ⊕ **Lieut., M. C., U. S. Army,** Jersey City, N. J.; Fordham University, New York City, 1915; aged 27; who at his entrance into the service served at Fort Oglethorpe, Ga., and then after courses of instruction at Bellevue Hospital and the Rockefeller Institute, New York City, was sent to Camp Greene, N. C., and later to the base hospital at Fort McHenry, Md., and overseas to serve with the American Expeditionary Forces; died at U. S. Base Hospital No. 78, Toul, France, February 5, from pneumonia.

John James Mott, Statesville, N. C.; Jefferson Medical College, 1866; aged 84; a member of the legislature in Catawba County in 1866 and 1867; president of the Western North Carolina Railroad from 1868 to 1872; collector of internal revenue for the sixth district of North Carolina from 1872 to 1882; for several years president of the Statesville Air Line Railway Company, and since 1912 president of the Radford (Va.) Water Power Company; died at Radford, January 28, from disease of the heart and bladder.

William Frederick Mittendorf ⊕ New York City; College of Physicians and Surgeons in the City of New York, 1873; aged 74; a specialist in ophthalmology; a member of the American Academy of Ophthalmology and Otolaryngology, American Ophthalmological Society and New York Academy of Medicine; consulting ophthalmologist to St. Mark's Hospital, and ophthalmic surgeon to the Nursery and Child Hospital, New York City; died at his country home in Crugers, N. Y., February 14.

Mary E. Walker, Oswego, N. Y.; Syracuse (N. Y.) Medical College, 1855; aged 86; lieutenant and assistant surgeon, U. S. Army, during the Civil War; awarded the Congressional medal of Honor for "bravery and valuable services in the field." noted as a dress reformer and advocate of equal suffrage; died at Bunker Hill, near Oswego, February 21.

Samuel G. Stewart, Topeka, Kan.; Starling Medical College, Columbus, Ohio, 1873; aged 73; a member of the Kansas Medical Society; chief of the medical staff of Christ Hospital, Topeka; consulting physician to the Topeka State Hospital; professor of principles and practice of medicine and clinical medicine in Kansas Medical College, Topeka; died at his winter home in St. Cloud, Fla., February 7.

Richard E. Hinman, Atlanta, Ga.; New York Homeopathic Medical College, 1889; aged 69; a member of the Medical Association of Georgia; a member of the faculty of the Atlanta Southern Dental College; for several years associate secretary and treasurer of the homeopathic board of the State Medical Examining Board of the State of Georgia; died at his home, February 10, from pneumonia.

Pierson Constantine Cope ⊕ Braddock, Pa.; University of Pittsburgh, 1890; aged 58; a member of the staff of the Braddock General Hospital; died at his home, February 25, from the effects of a gunshot wound of the head, believed to have been self-inflicted, with suicidal intent, while despondent over impaired health after an attack of influenza and a cerebral hemorrhage.

Henry Reuben Weston ⊕ **Lieut., M. C., U. S. Army;** University and Bellevue Hospital Medical College, 1903; aged 40; a member of the Association of Military Surgeons of the United States; who entered the Medical Reserve Corps in 1908, and had two tours of duty in the Philippine Islands; died, November 27, from gangrene of the lungs.

Alfred C. Goudy, Beach City, Ohio; Sterling Medical College, Columbus, Ohio, 1882; aged 58; for eighteen years a member and for several years president of the board of directors of the Stark County workhouse; local surgeon for the Baltimore and Ohio System; died at his home, February 9, from acute dilatation of the heart.

David Halsey Parliament ⊕ **Lieut., M. C., U. S. Army,** Covington, Ga.; Georgia College of Eclectic Medicine, Atlanta, 1911; Atlanta (Ga.) School of Medicine, 1913; aged 35; professor of chemistry and urinalysis in the Georgia College of Eclectic Medicine, Atlanta; died at Camp Dix, N. J., October 2, from pneumonia.

Leo Cassius Miller ⊕ **Lieut., M. C., U. S. Army,** Champaign, Ill.; University of Illinois, Chicago, 1906; aged 36; who served at Camp Greenleaf, Fort Oglethorpe, Ga., and was then ordered to the Embarkation Hospital, Camp Stewart, Va., in November, 1918; died at Champaign, December 14, from pneumonia following influenza.

James J. Beaton ⊕ **Lieut., M. C., U. S. Army,** Waycross, Ga.; Atlanta (Ga.) School of Medicine, 1909; aged 31; who entered the Army at Camp Grant, Rockford, Ill., and was transferred thence to Camp Lee, Petersburg, Va., for special duty and later to Hoboken and Camp Merritt, N. J.; died at Camp Merritt, February 8.

George Hudson, Stillwater, N. Y.; Albany (N. Y.) Medical College, 1882; aged 68; a member of the Medical Society of the State of New York; a member of the village board of health, president of the village board of education, and for several terms president of the village; died at his home, January 30, from appendicitis.

Elias Cameron Crummey ⊕ **Capt., M. C., U. S. Army,** Jesup, Ga.; Atlanta College of Physicians and Surgeons, 1905; aged 47; secretary of the Wayne County Medical Society from 1915 to 1917; on duty at Camp Wadsworth, Spartansburg, S. C., Died, November 26, from bronchopneumonia.

John Allen MacCormick ⊕ Boston; Harvard Medical School, 1902; aged 45; assistant in the outpatient department of the Free Hospital for Women, Brookline, Mass.; visiting gynecologist to Tremont Dispensary, Boston; died in St. Elizabeth's Hospital, Boston, February 16, from uremia.

Thomas Goodglick ⊕ **Lieut., M. C., U. S. Army,** Seattle; College of Physicians and Surgeons in the city of New York, 1916; aged 25; on duty with the Aviation Section, Signal Corps, in Oregon; died at North Bend, Ore., November 8, from bronchial pneumonia following influenza.

John Bishop Hazel, Hoopeston, Ill.; Hospital College of Medicine, Louisville, Ky., 1883; aged 69; a member of the Illinois State Medical Society and a specialist in diseases of the eye, ear, nose and throat; died at his home, January 20, from heart disease following influenza.

Harry D. Baldwin, Elyria, Ohio; New York Homeopathic Medical College, New York City, 1875; aged 64; at one time a member of the Ohio State Medical Association; a member of the staff of the Elyria Memorial Hospital; died at his home, February 25, from heart disease.

⊕ Indicates "Fellow" of the American Medical Association.

Alexander Lowry Ivins ⊕ Sayville, N. Y.; New York Homeopathic Medical College, New York City, 1911; aged 33; for several years surgeon of copper companies in Peru and Chile; died in King's Hospital, Bay Shore, L. I., N. Y., from pneumonia following influenza.

Albert S. Sherrick, Alverton, Pa.; Western Reserve University, Cleveland, 1885; aged 56; died at his home, February 11, from the effects of injuries received the day before, when he was struck by a street car while returning from making a professional call.

Charles Aubrey Bucklin, New York City; Bellevue Hospital Medical College, 1875; aged 64; instructor in diseases of the eye, ear, nose and throat in his alma mater in 1892; died at the home of his daughter in Glasgow, Scotland, February 13.

William P. Painter, Darby, Pa.; Jefferson Medical College, 1875; aged 76; for several years in the United States service; vice president of the First National Bank of Darby, and director of the Lansdowne Trust Company; died at his home, February 14.

William Glenn McKinney ⊕ Pittsburgh and Pitcairn, Pa.; University of Pennsylvania, Philadelphia, 1894; aged 50; local medical examiner for the Pennsylvania Railroad; died at his home, about February 25, from pneumonia following influenza.

John Little, Jr., Tuscaloosa, Ala.; Tulane University, New Orleans, 1889; aged 77; a member of the Medical Association of the State of Alabama; vice president of the Federal Savings Bank, Tuscaloosa; died at his home, February 1.

George P. Blundell, Yazoo City, Miss.; Tulane University, New Orleans, 1875; aged 71; at one time a member of the Mississippi State Medical Association; a Confederate veteran; also a pharmacist; died at his home, February 12.

John Palmer Matthews ⊕ Carlinville, Ill.; Marion-Sims College of Medicine, St. Louis, 1892; aged 51; local surgeon of the Q., C. and St. L. Railroad; died at his home, January 23, from septicemia due to an infected tooth.

Edward Benjamin Harrell, La Ceiba, Honduras, Central America; Tulane University, New Orleans, 1888; at one time sheriff of San Jacinto County, Texas; died at his home, February 6, from pneumonia following influenza.

Walter Wesley Rhyan, La Vina, Calif.; Starling Medical College, Columbus, Ohio, 1903; aged 46; formerly assistant physician and surgeon to the Esmeralda General Hospital, Goldfield, Nev.; died at his home, February 18.

Hiram A. Wood, Houston, Texas; Chattanooga (Tenn.) Medical College, 1895; aged 54; died in the Baptist Sanitarium, Houston, February 18, from the effects of burns accidentally received at his home, two days before.

Carlos E. Bowman, Alden, N. Y.; University of Buffalo, N. Y., 1883; aged 62; health officer and for several years president of the village and town of Alden; died in Escondido, Calif., February 7, from pneumonia.

Blaney William Cox ⊕ **Lieut., M. C., U. S. Army**, Goldesboro, N. C.; North Carolina Medical College, Charlotte, 1915; aged 30; a specialist in neurology; died, October 8, from pneumonia following influenza.

Thomas A. Strasser, Reading, Pa.; University of Pennsylvania, Philadelphia, 1867; aged 73; at one time county physician of Lehigh County; died at the home of his daughter in Reading, February 16.

George Edwin M. Herbst, Friedensburg, Pa.; Jefferson Medical College, 1878; aged 61; for several years a representative from Berks County in the state senate; died at his home, February 17.

Joseph Mellor, Cleveland; University of London, England, 1861; aged 78; the first city milk inspector of Cleveland; who served in India during the Indian mutiny; died at his home, February 15.

Stephen D. Lyles, Wagoner, Okla. (license, Oklahoma, act of 1908); aged 60; at one time a member of the Oklahoma State Medical Association; died at his home, February 1, from heart disease.

George William Salter, Brooklyn; Eclectic Medical College of the City of New York, 1895; aged 68; was found dead in his office in Brooklyn, February 11, from heart disease.

Charles Edgar Holbrook ⊕ **Lieut., M. C., U. S. Army**, Montreal, Que.; McGill University, Montreal, 1908; aged 33; died in the Royal Victoria Hospital, Montreal, October 18.

Alexander L. Pomeroy, Windsor, Ohio (license, Ohio, 1896); aged 96; at one time a member of the Ohio State Medical Association; died at his home, February 10.

George Jacob Stubenrauch, Chicago; University of Illinois, Chicago, 1910; aged 46; at one time a member of the Illinois State Medical Society; died at his home, February 23, from angina pectoris.

Lewis Henry Plimpton, Norwood, Mass.; Harvard Medical School, 1879; aged 68; a member of the Massachusetts Medical Society; died suddenly in Boston, February 21, from heart disease.

Frank Martin Dedaker ⊕ **Lieut., M. C., U. S. Army**, Gloucester City, N. J.; University of Louisville, Ky., 1910; aged 31; died at his home, October 6, from pneumonia following influenza.

Harriet Hooton Hanna Hubbell, San Francisco; Cooper Medical College, San Francisco, 1890; aged 72; died at St. Luke's Hospital, San Francisco, February 16, from arteriosclerosis.

Henry Bobb, East Greenville, Pa.; University of Pennsylvania, Philadelphia, 1868; aged 72; died suddenly in the home of his daughter in Philadelphia, February 20, from heart disease.

Myron Levi Chamberlain ⊕ Boston; Bellevue Hospital Medical College, 1867; aged 74; a medical cadet, U. S. Army, during the Civil War; died at his home, February 13.

John R. Elder, Bear Branch, Ind.; Kentucky School of Medicine, Louisville, 1905; aged 39; died at his home, February 20, from pneumonia following influenza.

James W. McCarty, Owensboro, Ky.; Louisville, Ky., Medical College, 1876; aged 70; a member of the Kentucky State Medical Association; died, December 31.

Eben W. Keeney, Newport, Ky.; Medical College of Ohio, Cincinnati, 1870; aged 70; a member of the Kentucky State Medical Association; died, December 4.

John Cleon Kerr ⊕ **Lieut., M. C., U. S. Army**, Hazlewood, Pittsburgh; University of Pittsburgh, 1912; aged 31; died October 27, from bronchopneumonia.

Leonard Alling Shepard, Berkeley, Calif.; Miami Medical College, Cincinnati, 1873; aged 66; died at his home, February 17, from a nervous breakdown.

John R. Tuttle, Wheeling, Ind. (license, Indiana, 1897); aged 61; a practitioner for thirty-six years; died at his home, February 21, from nephritis.

Harold Ward Pyle ⊕ Oberlin, Ohio; Cleveland Homeopathic Medical College, 1897; aged 47; died at his home, February 13, from heart disease.

Cecilius Calvert Steuart ⊕ Baltimore; University of Maryland, Baltimore, 1882; aged 58; a specialist in pediatrics; died at his home, February 14.

William Creighton Bloomer, Cleveland; Starling Medical College, Columbus, Ohio, 1898; aged 49; died at his home, February 5, from pneumonia.

John Collier Laidley, Carmichaels, Pa.; University of Pennsylvania, Philadelphia, 1895; aged 50; died at his home, about February 25, from influenza.

John M. Campbell, Saginaw, Mich.; McGill University, Montreal, 1890; aged 71; died at his home, February 7, from disease of the stomach.

W. Sanford Kemp, Dayton, Ohio; Eclectic Medical Institute, Cincinnati, 1866; aged 75; died at his home, February 15, from heart disease.

John M. Suttles, Atlanta, Ga.; Southern Medical College, Atlanta, 1884; aged 69; died in a private sanatorium in Atlanta, January 28.

Henry S. Haskin ⊕ Highland Park, Ill.; University of Michigan, Ann Arbor, 1872; aged 69; died suddenly at his home, February 16.

Daniel Bodifield, Cleveland; American Eclectic Medical College, 1878; aged 87; died at his home, February 5, from acute gastritis.

Sophronia A. Thomlinson, Shiloh, N. J.; Woman's Medical College of Philadelphia, 1878; aged 80; died at her home, February 14.

Alonzo Dow Husted ⊕ Pittsburgh; University of Worcester, Cleveland, 1887; aged 63; died at his home, about February 25.

Jacob Ernest Brecht ⊕ Fort Myers, Fla.; Washington University, St. Louis, 1874; aged 76; died at his home, January 6.

Irving Etienne Richard, Providence, R. I.; Jefferson Medical College, 1916; aged 27; died at his home, January 26.

Herbert H. Howe ⊕ Yantic, Conn.; University of Vermont, Burlington, 1880; aged 65; died, February 4.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

EVADING A FRAUD ORDER?

Has "Orchis Extract" of the "Packers Product Company" Become "Organo Tablets" of the "Organo Product Company?"

Inquiries have recently come to the Propaganda department regarding the Organo Product Company, 11 West Randolph Street, Chicago, which sells "Organo Tablets" as a cure for "lost vitality"! When the first inquiries came in, no advertising matter accompanied them. Investigation showed that 11 West Randolph Street was the headquarters of a "men's specialist," one John G. Gill, long identified with Chicago quackery.

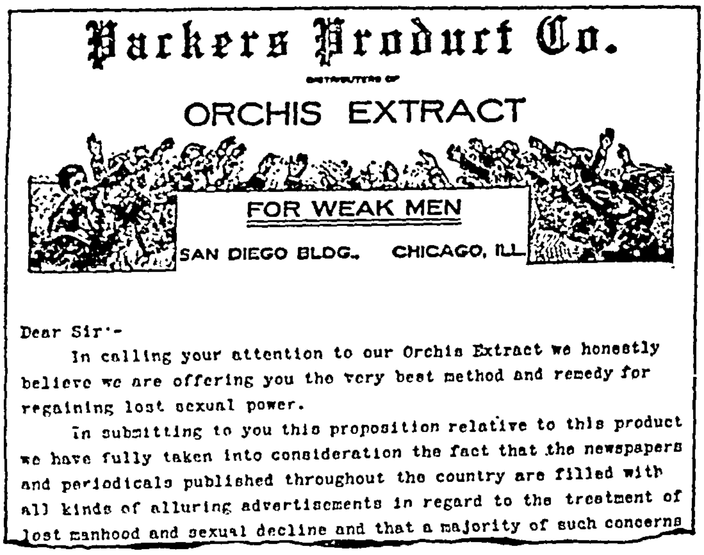
For several years Gill operated a medical mail-order fakery, known as "The Edson Institute," Chicago. He abandoned the business when the federal authorities began to make it uncomfortable. Later, he was connected with one Burgess, another advertising quack in Chicago, himself a hireling of a syndicate of quacks. Gill left Burgess after a few months, to take a position with a similar fakery, known as "Dr. White, Specialists." A reporter for the Chicago *Tribune*, whose exposures of Chicago's quacks have made the "advertising specialist" business in that city a rather hazardous commercial undertaking, stumbled on to the "White" fakery and gave it some very unpleasant publicity. As a result "Dr. White"—which was not his name—left Chicago between days, owing John G. Gill $500. So, at least, Gill claimed when he was called before the Department of Registration and Education of the State of Illinois, to answer some rather pointed questions about his quackish activities. Further, according to Gill's testimony, he (Gill) brought suit against, and made a levy on the office fixtures left behind by White. These fixures were sold on attachment by the bailiff of the municipal court, and, according to Gill, were purchased by Fred A. Leach, from whom Gill claims he is buying them on the instalment plan.

This brings us to Mr. Leach. Some of our readers will remember that Fred A Leach operated the Packers Product Company, a mail-order fraud that sold "Orchis Extract," until it was put out of business by the government in April, 1918. Leach has been in the mail-order business for a good many years. He was manager of the "Distributors' Guarantee Association," against which a fraud order was issued in 1908; under the name of "Vacuum System" and "David Kuno" he sold vacuum developers for the alleged enlargement of the penis; and under the name of "The Ausin System" he also handled vacuum developers and later yet sold similar devices under the name of the "Wade Manufacturing Company."

These facts pointed to a probable community of interest between the "Organo Product Company" of 11 West Randolph Street, and its "Organo Tablets," and the fraudulent "Packers Product Company" and "Orchis Extract." Then came some of the advertising matter of the Organo Product Company. Even a superficial comparison of the circular letters and booklets used in exploiting Organo Tablets showed the close resemblance between this humbug and the government-declared fraud—Orchis Extract of the Packers Product Company. The wording of the letters and booklets is almost identical. Even an old testimonial for Orchis Extract appears (under a new address) for Organo Tablets. Compare, for instance:

TESTIMONIAL FOR ORCHIS EXTRACT	TESTIMONIAL FOR ORGANO TABLETS
"Mound City, Mo.	"Louisville, Ky.
"*Gentlemen:*—Enclosed find $2 for which please send me one more package of Orchis Extract. I think it is helping me so I am going to continue the use of it until I think I am cured."	"*Gentlemen:*—Enclosed find $2 for which please send me one more package. I think it is helping me, so I am going to continue the use of it until I think I am cured."

Doubtless when the facts detailed above are brought to the attention of the federal authorities, an investigation will be made. Then, possibly, it may be necessary to extend the fraud order issued against the Packers Product Company to cover the Organo Product Company.



Packers Product Co.

DISTRIBUTORS OF

ORCHIS EXTRACT

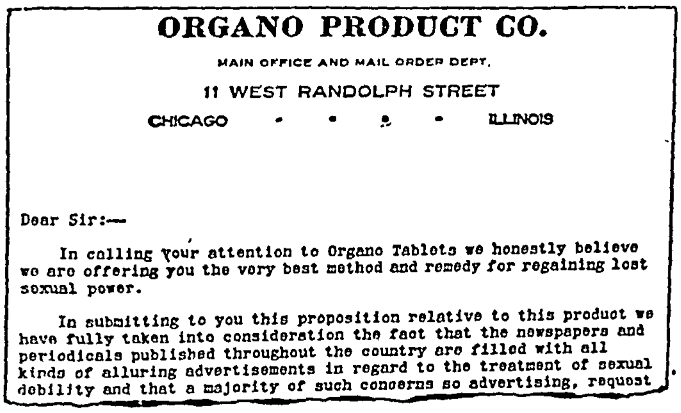
FOR WEAK MEN

SAN DIEGO BLDG., CHICAGO, ILL.

Dear Sir'-

In calling your attention to our Orchis Extract we honestly believe we are offering you the very best method and remedy for regaining lost sexual power.

In submitting to you this proposition relative to this product we have fully taken into consideration the fact that the newspapers and periodicals published throughout the country are filled with all kinds of alluring advertisements in regard to the treatment of lost manhood and sexual decline and that a majority of such concerns



ORGANO PRODUCT CO.

MAIN OFFICE AND MAIL ORDER DEPT.

11 WEST RANDOLPH STREET

CHICAGO • • • • ILLINOIS

Dear Sir:—

In calling your attention to Organo Tablets we honestly believe we are offering you the very best method and remedy for regaining lost sexual power.

In submitting to you this proposition relative to this product we have fully taken into consideration the fact that the newspapers and periodicals published throughout the country are filled with all kinds of alluring advertisements in regard to the treatment of sexual debility and that a majority of such concerns so advertising, request

Facsimiles (reduced) of part of two circular letters sent out by the Packers Product Co. and the Organo Product Co., respectively. Notice the similarity of wording. The Packers Product Co. was the name under which one Fred A. Leach operated a fraud to which the federal authorities denied the use of the U. S. mails. Leach is now located at 11 West Randolph Street, Chicago, which houses the Organo Product Co. and "Dr. Gill, Specialist."

DEPILAGIENE

"Depilagiene," or, to give it its full title, "Franco-American Hygienic Depilagiene," is one of a large number of toilet preparations put on the market by the Franco-American Company of Chicago. In a booklet issued by the Franco-American Hygienic Company, we read that "Depilagiene is an objectionable hair remover," which seems to be the concern's way of saying that it is a remover of objectionable hair. An original bottle of Depilagiene was submitted to the A. M. A. Chemical Laboratory for examination, and the chemists' reported as follows:

"The bottle of Depilagiene contained 18.5 grams of a pink powder having an odor resembling that of oil of citronella. Qualitative tests showed the presence of barium, sulphur, sulphid, sulphate, and small amounts of aluminum and calcium; aromatic oils and a red dye were also present. Essentially, the product is a mixture of barium sulphate, barium sulphid, sulphur and starch. A quantitative investigation of the active ingredient, barium sulphid, was made, and disclosed the presence of 22.6 per cent. of this drug. As commercial barium sulphid contains only about 50 per cent. of the pure chemical, Depilagiene probably contains approximately 45 per cent. of the commercial drug."

It will thus be seen that Depilagiene has no claims to originality, as practically all the chemical "hair removers" are composed of some form of sulphid. Naturally, the preparation is likely to cause more or less irritation of the skin, the amount depending to some extent on the way in which it is used, and to an even greater extent on the tolerance of the individual skin. Like all chemical depilatories, the use of Depilagiene must make the hair coarse.

Correspondence

ANILIN, RATHER THAN NITROBENZENE, AS THE POISON IN SHOE DYE

To the Editor:—More than the usual amount of interest seems to be manifested in the cases of poisoning from shoe dye reported from Camp Johnston, and it would appear to be in the interest of our records of the effects of poisons to determine definitely just what was the poisonous agent in this case. Being connected with a company engaged for many years in the manufacture of the several substances which may here come under suspicion, I have had to give some attention to the effects as manifested in workmen. The gross appearance of the blood as described did not impress me as suggestive of poisoning by a nitro compound (nitrobenzene) but as poisoning by anilin. The effects of both of these substances are quite similar, but the nitro compounds are more likely to bring about a destruction of the red cells and cause the blood to present the appearance of chocolate; while anilin is more likely, at least in its early stages, to cause the dark (asphyxiated) condition described. Anilin is quicker in its action and more quickly recovered from, but, more important from the standpoint of the present case, shows a particular predilection to penetrate leather and rapidly poison by skin absorption, so that we have been obliged to take special precautions regarding the shoes worn by anilin workmen. Both agents will cause cyanosis.

Nitrobenzene is widely used as a cheap perfume, and while it was probably present in some proportion in the preparation used by "Toney," I am tolerably confident that a chemical examination will show a much larger proportion made up of anilin, used as a solvent or mordant for the dye which gives the leather its desired color.

W. G. Hudson, M.D., New York.
Medical Director, E. I. du Pont de Nemours & Co.

"A NEW TREATMENT FOR THE MORPHIN HABIT"

To the Editor:—The article by Dr. C. S. Bluemel on "A New Treatment for the Morphin Habit" (The Journal, Feb. 22, 1919, p. 552) is based on such unwarranted assumptions that it should not pass unnoticed. Dr. Bluemel states that (1) the "immunity" (tolerance) is probably due to the presence of an antibody or antitoxin in the blood, and that (2) physicians have come to believe that a definite antibody to morphin is formed in the blood, and that the unneutralized antibody is the cause of the withdrawal symptoms.

The first statement, so far as is known, is without any basis of fact. Alkaloids do not produce antibodies. This has been established by many investigators. It would be perhaps more in accord with the facts to say that many investigators have failed to find evidence that anything except protein produces antibodies. In view of this, if Dr. Bluemel has any definite evidence to the contrary he should have stated it in his article. Even when antitoxins are formed, they act only to neutralize toxins. They exert no direct action on the body cells (Ehrlich, Behring) and could therefore not account for the withdrawal symptoms of morphin. Now, it is quite possible that the view of Ehrlich and Behring is wrong. It is also unfair to ask any one to accept their opinion unqualifiedly; but the reputation of these men is such that those who disagree with them should give some basis more adequate than "purely theoretical considerations." Dr. Bluemel has given no adequate support for his opinion. Physicians have no reason for this belief, and I am of the opinion that relatively few hold such a view.

The result of Dr. Bluemel's treatment is not under discussion, since it is quite possible to get good results from a wrong hypothesis. However, even if we grant his assumption and admit that saline solution will aid such cases, there is no reason for giving this intravenously. This method is much abused and should never be used except for sufficient reason. Salt solution is so rapidly absorbed from the gastrointestinal tract and so devoid of action on the intestine that there is little excuse for giving it intravenously.

Hugh McGuigan, M.D., Chicago.

To the Editor:—The article by Dr. C. A. Bluemel on the treatment of the morphin habit is very interesting. The doctor has not given us statistics regarding the ultimate recovery of these patients from the disease of morphinism. This is the important point in the treatment of these cases. From personal investigations I know that withdrawing the drug from the patient is a simple process, provided the patient has been prepared beforehand by a few weeks' observation and preliminary reduction. What we are looking for in these cases is positive results. These are not obtained by one, two or three weeks of treatment, but rather by several months or years of careful observation and conscientious treatment of each individual case.

W. B. Reed, M.D., Rochester, N. Y.

HARMLESSNESS OF GLASS IN DIGESTIVE TRACT

To the Editor:—Forty-five years ago I was called to attend one boy, aged 4 years, and two girls, aged 5 and 6, who had eaten corn bread with powdered glass in it. The bread had been prepared to kill rats. I gave an emetic, followed in one hour with boiled potatoes, till the stomachs of the children were filled. In one hour I gave castor oil. The potatoes were expelled by rectum thoroughly mixed with fine glass. The children all recovered without any untoward symptoms.

A. H. W. Sullivan, M.D., Miami, Mo.

To the Editor:—One morning I was summoned to the house of an aged and infirm patron, who was temporarily caring for two of her orphan granddaughters, who were about 14 years of age; they were cousins and almost inseparable. They were in agony, making effort to evacuate the bowels without success, referring the intense pain to the region of the rectum. On digital examination I found the sphincters closely contracted and a mass of gritty substance. After making sufficient digital dilatation I was enabled to remove several ounces of broken glass from the size of coarse sand to that of grains of corn, followed by some venous hemorrhage, which was of short duration. After a brisk cathartic a prompt recovery followed without untoward results. My curiosity was naturally aroused as to the motive for the ingestion of the glass and the manner in which it was done. The girls informed me that they had been reproved by their grandmother for being out on the streets late at night and had been forbidden to repeat the performance. Considering that life was not worth living if they were to remain housed up without privileges of the gaieties of the outer world, they formed a compact that they would destroy their own lives and would never be separated. The manner of accomplishing it was the puzzling question. They preferred poison, but knew it was impossible to procure any. One of them remembered hearing that feeding a dog with pounded glass incorporated in his food was sure death. They found two beer bottles and took them to a toilet in the rear of the dwelling. With a hammer they pounded the bottles on the floor as fine as they could in separate places, so that each might get an equal amount. They directed me to the place, where I found the unmistakable evidence. One of the bottles was bluish and the other transparent, corresponding with the glass I had removed.

G. J. C. Wintermute, M.D., Celina, Ohio.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

MEDICAL EXEMPTIONS IN INCOME TAX

To the Editor:—Will you kindly inform me if roentgen-ray plates and replacement of roentgen-ray tubes can be deducted as business expense in the income tax report?

L. Amster, M.D., Atlanta, Ga.

Answer.—Roentgen-ray plates and tubes, while equipment, would come under the same head as drugs, bandages, etc., because they are constantly breaking and have to be replaced. The cost of roentgen-ray machinery would, of course, be an investment, but the upkeep of the machine and the cost of replacement of material would be an expense.

To the Editor:—1. I noticed your editorial on preparing income tax accounts. This has been exceedingly puzzling to me as I am an oculist doing refraction work, and, being situated inland, have to furnish the glasses for my patients. The "glasses" are merchandise, and I am supposed to report the merchandising profit on the glasses besides any professional charge that I may incorporate in the total charge for the glasses, keeping the two items separate. I am not able to do so. What should I do? 2. Please advise what annual depreciation you would think fair on a medical library, surgical instruments and office furniture and fixtures.

J. C. McAllister, M.D., Ridgway, Pa.

Answer.—1. If your bookkeeping methods do not enable you to separate the mechandising profit on glasses furnished patients from your charges for professional services, you will have to make an estimate, as nearly accurate as possible, for the 1918 return. It would be advisable, however, to modify your bookkeeping methods so as to separate these items in the future.

2. The maximum annual depreciation of an article should not be greater than the original cost of the article, divided by the number of years it can be used. A physician's library is a permanent investment, and is not supposed to wear out or become useless; therefore, no depreciation could be estimated. Depreciation on instruments, furniture and fixtures should be the original cost divided by the number of years in which they can be used, or are of any value.

To the Editor:—May I suggest publication of the following example, issued by a local banking institution to aid physicians who are having difficulty in making their income tax statements.

A. R. C.

Answer.—The example follows: George Lee is a physician supporting a family consisting of his wife, two children under age and two over 18 years of age. He owns an automobile which he uses both in his professional work and for pleasure, fully three fourths of its use being for business. During 1918 the cost of running the automobile, including the salary of his chauffeur, was $1,456; gasoline, repairs and other expense, $1,638.25; insurance, $53.85. The depreciation of the automobile is estimated at $150, one tenth of its original cost. During the year the doctor spent $437 for club and lodge dues, entertainment, etc., which he charges to an account called "good will promotion." To the same account he charges $200 which he donated to the local charity organization and $17 which was his expense on a short trip to give a free lecture for a local Y. M. C. A. He spent $460 during the year attending medical conventions, $36 for medical journals and dues for medical societies, and $300 for books and instruments of a permanent value. His office and traveling expenses were $14,948.40 for the year. His professional fees amounted to $30,653 for the year, and in addition he received $419.30 as compensation for a short period which he served in the army before the armistice. He spent $600 for uniforms, equipment, etc., when in the army. Dr. Lee also owned a house which he rented during the year for $1,356. The expenses for repairs, insurance, etc., on this house were $16.06, and the depreciation is estimated at $200. The taxes on this rented property and on the home of Dr. Lee amounted to $509.19. The doctor's wife received $95 as interest on a mortgage. How will Dr. Lee report his net income? Answer: The gross income from services will include the professional fees, amounting to $30,653, but not the compensation received in the army. From this will be deducted the office and traveling expenses, three fourths of the automobile expense and depreciation, expenses of attending conventions, and the cost of medical journals and societies, a total of $17,917.97, making his net income from services $12,735.03. The club dues, etc., and the cost of army equipment are personal expenses. The cost of books and implements is not deductible, but the doctor should carry a property account and charge off a depreciation and obsolescence allowance on such property. The net income from the rented property is $1,139.94. The interest on Mrs. Lee's mortgage will be included on the doctor's return. The taxes will be deducted as will the $200 charitable donation. The $17 is deductible because it was an expense and not a donation, although incurred in a charitable enterprise. The total net income was therefore $13,085.78, on which the normal tax, deducting the $2,400 exemption, is $1,042.29, the surtax $244.29, and the total tax is $1,286.58. Adding the $5.70 normal tax on the income of Mrs. Lee, the total tax as shown by the return is $1,292.28.—1919 Federal Income and War Tax Laws, Halsey, Stuart & Co.

CREEPING ERUPTION: LARVA MIGRANS

To the Editor:—I have a patient who has a parasitic skin disease due to a burrowing animal parasite. The track of the parasite is plainly visible as a very fine red line under the horny layer. It seems to work mainly at night, when an intense itching takes place. At the end of the track is a slightly elevated papule. I should be glad to have you inform me as to the name of this parasite. I have recently seen two patients similarly infected, one on the dorsal surface of the left thumb, and the other on the anterior surface of the left thigh. I have employed tincture of iodin with indifferent results, the iodin serving mainly to stop the working of the parasite, when after a period of quiet it would resume its excursions again.

A. E. Conter, M.D., Apalachicola, Fla.

Answer.—This condition is also known as larva migrans, and is produced by the wandering in the skin of a larva which leaves behind it an inflammatory track. The larva wanders indefinitely under the skin and produces a narrow red line which is slightly raised. It usually travels at the rate of an inch or more a day. The direction is not regular. The most active part of the line is the advancing end. The larva itself is usually found a quarter of an inch or more in advance of the active advancing end of the line, and is denoted by itching or burning. The treatment consists in destroying the larva. Hutchins, in the *Journal of Cutaneous Diseases*, 1906, suggested the injection of cocain solution followed by the injection of one or two drops of chloroform, the needle being inserted behind the advancing end of the track and pushed forward to the probable location of the parasite. Stellwagon cured several cases by incision with mercuric chlorid and the application of a minute quantity of nitric acid to the suspected site of the parasite. A general discussion of the subject appeared in The Journal, Jan. 15, 1916, p. 172, in an article by Knowles.

A Great Responsibility on the Profession.—According to the regulations of the Ontario (Canada) License Board, a duly qualified medical practitioner is legally entitled to carry in his house or in his office 10 gallons of liquor. He can procure 1 quart for medical practice from any qualified druggist, or he can purchase from a vendor or distiller any quantity up to 10 gallons. When the physician in his judgment considers a larger quantity of liquor necessary for his patient than the prescribed 6 ounces, he can issue a prescription for 1 dozen bottles of ale, beer or porter containing not more than three half pints each, or 1 quart of wine or distilled liquor, which can only be procured from one of the seven vendors of Ontario. None of the foregoing liquor mentioned can be legally used for beverage purposes. All the provisions mentioned for procuring liquor are absolutely for medical use only.—From the *Canadian Practitioner and Review.*

REPORT OF THE SIXTH EXAMINATION OF THE NATIONAL BOARD OF MEDICAL EXAMINERS

The sixth examination of the National Board of Medical Examiners was held in Chicago and New York, Dec. 2-19, 1918. The written examinations were held simultaneously in the two places. The laboratory and clinical examinations immediately followed the written examination at Chicago, while in New York this part of the examination was held from the 14th to the 19th of December. The subjects of the examination and the relative value of each were: anatomy, 100; physiology, 75; chemistry, 75; pathology, 75; bacteriology, 50; materia medica, pharmacology and therapeutics, 75; medicine, 200; surgery, 200; obstetrics and gynecology, 75; hygiene and sanitation, 50; medical jurisprudence, 25. A percentage of 75 was required to pass. Falling below 65 per cent. in two subjects, or below 50 in one subject, constituted a failure.

There were eighty-nine applicants who applied for examination. Seventy were found to have the essential preliminary and medical qualifications, but owing to the epidemic of influenza and to many candidates having been called into service, only sixteen appeared for examination, of whom fifteen passed and one failed. The following colleges were represented:

PASSED

FAILED

Rush Medical School	1918

In the case of candidates from the Rush Medical School, the M.D. certificate is withheld pending the completion of the one year internship. For successful candidates who have not completed their intern year, the board's certificate is withheld pending the completion of that work.

The general average of candidates is based on subject values as rated by the board.

EXAMINATIONS AND TIME ALLOWED

Subject	Kind of Examination	
	Written	Other, and Remarks
Anatomy	3 hours	Oral with prepared spec. 20 min. for each candidate
Chemistry	3 hours	Two hours laboratory in physiologic chemistry
Physiology	3 hours	Laboratory 2 hours
Pathology	3 hours	Laboratory exam., 20 min. each cand.
Bacteriology	2 hours	Laboratory 2 hours
Materia medica, pharmacology and therapeutics	3 hours	Laboratory 2 hours
Medicine	3 hours	Clinical lab., 1 hour each cand.; clinical med., 3 hours
Surgery	3 hours	Lab. op. surg. and applied anatomy, 3 hours; clin. exam., 3 hours
Eye, ear, nose and throat	....	Clinical exam., 30 min. each candidate
Dermatology	....	Clinical exam., 30 min. each candidate
Obstetrics and gynecology	3 hours	
Hygiene	2 hours	
Medical jurisprudence	2 hours	

Iowa December Examination

Dr. G. H. Sumner, secretary of the Iowa State Board of Medical Examiners, reports the written examination held at Des Moines, Dec. 10-12, 1918. The examination covered 8 subjects and included 100 questions. An average of 75 per cent. was required to pass. Seven candidates were examined, all of whom passed. The following colleges were represented:

College PASSED	Year Grad.	Per Cent.
Chicago College of Medicine and Surgery	(1917)	87.2
Hahnemann Med. Coll. and Hosp. of Chicago	(1919)	87.2, 87.2, 87.6
Loyola University	(1917)	85.6
St. Louis College of Physicians and Surgeons	(1910)	80.1
Vanderbilt University	(1916)	81.6

Iowa Reciprocity Report

Dr. G. H. Sumner, secretary of the Iowa State Board of Medical Examiners, reports that 2 candidates were licensed through reciprocity at the meeting held Jan. 6, 1919. The following colleges were represented:

College LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
College of Physicians and Surgeons, Chicago	(1905)	Missouri
University of Pennsylvania	(1902)	Penna.

Book Notices

Gasoline and Kerosene Carburetors: Construction, Installation, Adjustment. A Simple, Comprehensive Treatise for Practical Men, Explaining All Principles Pertaining to Carburetors for All Types of Internal Combustion Engines Intended to Operate on Liquid Fuels Such as Gasoline, Kerosene, Benzol and Alcohol; All Leading Types of Carburetors and Their Adjustment Are Fully Described. By Victor W. Pagé, M.S.A.E. Invaluable to Repairmen, Students and Motorists; Includes the Most Complete Exposition on Kerosene Carburetors Ever Published. Cloth. Price, $1.50. Pp. 206, with illustrations. New York: Norman W. Henley Publishing Company, 1919.

This is a simple treatise explaining basic principles pertaining to carburetion, and showing how liquid fuels are vaporized and turned into gas for operating all types of internal combustion engines intended to operate on vapors of gasoline, kerosene, benzene and alcohol. Several types of carburetors are described. Carburetion troubles, fuel system trouble, carburetor repairs and installation, and modern carburetor developments are considered in a thorough manner. This book will prove a convenience to physicians owning automobiles.

Neoplastic Diseases: A Text-Book on Tumors. By James Ewing, A.M., M.D., Sc.D., Professor of Pathology at Cornell University Medical College. Cloth. Price, $10 net. Pp. 1027, with 479 illustrations. Philadelphia: W. B. Saunders Company, 1919.

Since the very beginning of the study of tumors, the tendency has been to divide them into large groups or classes, and to regard representatives of the same group occurring in different places not merely as more or less closely related but as essentially identical and equivalent. We are in the habit of thinking of sarcoma as pretty much the same thing no matter what organ or tissue is involved primarily, and the same is true with regard to carcinoma and also other tumors. We have searched for one universal cause of cancer, and we speak commonly of the unknown cause of cancer as if there could be no question that malignancy is due to one definite, principal causative agent, which, of course, remains to be proved. In the efforts to devise simple, easily understood, and all-inclusive schemes for an orderly classification of tumors, the temptation naturally arises to subordinate and minimize many more or less obvious differences in the mode of origin and behavior of related but not identical or equivalent tumors. The centralizing point of view here indicated, the outcome largely of the influence of preconceived notions, is not conducive to progress, but tends rather to retard the growth of knowledge; it is therefore refreshing to find that the author of this new and imposing work on tumors has been under the spell of a larger and clearer vision. As indicated by the title—"Neoplastic Diseases"—tumors are here presented as specific diseases or clinical and pathologic entities, the essential facts in regard to which can be revealed fully only as intensive study is given to special forms and cases. The endeavor has been, to quote from the preface, "to analyze the numerous etiologic factors which meet in such diverse fashions in the inceptions of tumors, to emphasize the general dependence of clinical cause upon histologic structure, to trace the histogenesis to the last degree, impressing its essential importance when known, and to enumerate and contrast the more striking clinical features which are often highly characteristic of different tumors." We see that particularization rather than contemplation of general oncologic principles is the keynote. The contents are in two parts: The first, general oncology, occupies 148 pages and deals with historical matters, the matter of definition, malignancy, metastasis, chemistry and serology, theories in regard to cancer, special etiology, and experimental cancer research. The second part, special oncology, covers about 800 pages, and considers the particular forms of tumors and the tumors of the individual organs. There are extensive lists of references to the more important literature, and a large number of satisfactory illustrations almost wholly photographic; the microscopic structure of practically every form of tumor (except xanthoma) is reproduced. The title page states that this is a textbook on tumors; but it is much more extensive and detailed than the usual textbook, and it addresses itself especially to readers looking for complete information. It is a masterly production, the result of the earnest labor of many years; the style is lucid, fresh, vigorous; the discussion is extremely well advised, without bias, and adequate. There is, in fact, no other book that renders accessible in so well assimilated form so much knowledge in regard to the histogenesis and structure of all varieties of tumors.

The Humane Society of the Commonwealth of Massachusetts: An Historical Review 1785-1916. By M. A. DeWolfe Howe. Boards. Pp. 398, with illustrations. Cambridge: Riverside Press, 1918.

The Massachusetts Humane Society published its first pamphlets in 1787, and has continued its work since that time. The present book is based on the publications of the society. It is a beautifully prepared volume both as to typography and illustrations.

The work of a humane society comes very near to that of the medical profession. A humane society was organized in Philadelphia in 1780. Dr. Benjamin Say was the president of this society in 1799, and Dr. Benjamin Rush of Philadelphia was an early honorary member of the Massachusetts society. In 1793 he sent the president of this society two pamphlets widely distributed in Pennsylvania, and from one of them the Massachusetts society published an extract in 1893 relative to avoiding the danger of drinking cold water while the body is heated. The instigator of the Massachusetts society was Dr. Moyes, the organization of the society being described in its articles published in 1786. The first president of the society was His Excellency, Governor Bowdoin, and Dr. John Warren was the second vice president. One of the first publications of the society concerned methods of treatment to be used with persons apparently dead from drowning. This included regulations relative to warming the body and securing a good air supply. Some of the directions are:

> No persons are to be admitted into the room but those who are actually employed in exerting their utmost endeavors for the recovery of the unfortunate; six persons are therefore the greatest number that can ever prove useful on such occasions; and those who are by-standers for the sake of curiosity should be requested to withdraw, as their presence may retard or totally prevent the restoration.
>
> The smoke of tobacco thrown up the fundament should be ranked among the earliest applications; if a fumigator should not be at hand, the common pipe will answer the purpose of applying this vapour to the bowels. So easy and important an operation should be repeatedly performed, as the good effects of tobacco smoke have been proved in many cases.

At the same time instruments were devised for inflating and extracting air from the lungs.

An interesting sketch of Dr. John Warren appears in the first chapter of the book, also one of Dr. Isaac Rand. In a diary kept by Dr. Ethan Elliott, a brother of Dr. Rand, is given a table of fees of that date, running from a visit 50 cents, to a consultation $1, double fees at night, capital operations in surgery £5, opening an abscess 50 cents, and extracting a tooth the same.

The first thirty years of the society's work were devoted chiefly to humane efforts attached to maritime interests. The records contain many accounts of the saving of persons from drowning and of rewards for such service, including also accounts of the establishment of life-saving stations along the shore. The third chapter is concerned with rescues and resuscitations, the greatest attention being given to the resuscitation of the drowned. This is an excellent description of the scientific development of such methods.

The society, however, did not devote itself entirely to such methods for the relief of humanity. In 1790 Rev. Jeremy Belknap, one of the founders of the Massachusetts Historical Society, proposed to the humane society the establishment of a foundling hospital, and a committee was appointed and recommended "a consultation with the Medical faculty, in order most effectually to provide 'for the sick-poor, for the assistance of lying-in women, and for foundlings.'" Through their efforts the Boston Dispensary was established in 1796. At a meeting in 1799 a prize of $50 was voted to be given "for the communication of the greatest number of important and well-substantiated facts instrumental in giving origin to the Yellow Fever in the United States." The paper which won the prize was that of Dr. Samuel Brown of Lexington, Ky.

These are but a few of the interesting points brought out in this historical review, which carries the work of the humane society up to recent date. While of chief interest to those having an actual part in the work, the volume will have interest for all others who believe that "it is a pleasant exercise of the imagination to look upon old things as new, to acquire the realizing sense that a long established institution was once precisely as new as the newest organization of the present year and month with all its work to be done and all its history and traditions to be made."

Social Medicine, Medical Economics and Miscellany

Report of International Health Board

The report of the International Health Board for 1917, just issued, shows that notwithstanding the war, infection surveys were conducted in Tobago, Cayman Islands, Papua; demonstrations in relief and control of hookworm disease were carried on in twelve states in this country and twenty-two foreign states and countries; a beginning was made in the control of hookworm in mines by conducting a preliminary infection survey in mines in China; there was cooperation with the American Red Cross and with the French government in measures for the control of tuberculosis in France; experiments were conducted in Arkansas and Mississippi for the purpose of testing measures for the control of malaria; the yellow fever commission carried on survey work in Martinique and Venezuela; there was established and put in commission a hospital ship to bring medical and surgical relief to the inhabitants of the Sulu Archipelago, Philippine Islands; also a department of hygiene in connection with the Faculty of Medicine at the University of São Paulo, Brazil, and the completion of a scientific investigation of hookworm disease in Malaya, a report on which was made by the commission sent in 1915 to make the study.

The most extensive work of the board consisted in the efforts against hookworm. Two general outstanding features were the general improvement in sanitation in the regions investigated through the enactment of legislation aimed at the prevention of soil pollution, and the great increase in public appropriations in support and extension of the work. Two general plans have been followed in the hookworm work, the dispensary of the movable sort, which reaches a large number of people and is important for its educational value, and the intensive plan, in which a small area is selected and efforts are made to reach every inhabitant. The latter method gives a practical demonstration, in a limited area, of the possibility of controlling hookworm disease in all infected areas. At the same time it points the way toward the ultimate control of other preventable diseases by similar methods of direct attack. Of the drugs used the experience has been that thymol and chenopodium are most efficacious. In an experience with 13,000 cases in the South Sea Islands, scarcely an untoward symptom was encountered. Seventy-three per cent. of the persons treated in the Fiji Islands were cured by two treatments. Six months after treatment, reexamination showed that only 10 per cent. were reinfected. In an experiment it was shown that one treatment with chenopodium had an efficiency of 96 per cent., as compared with 89 per cent. for thymol, 47 per cent. for eucalyptus and 27 per cent. for beta-naphthol. In some countries, however, alarming symptoms and sometimes death followed the administration of chenopodium. Smaller doses are recommended. The Uncinariasis Commission found that the efficiency of 99 per cent. obtained by a single treatment with 3 c.c. of the oil divided into three doses and administered at hourly intervals was reduced to only 95 per cent. when the dose was cut in half, and untoward results were rare. Magnesium sulphate has been found to be the most efficient purgative after the oil.

An extended review of the hookworm situation in the various countries is contained in the report, the other activities of the board being given space commensurate with the extent of the work done, as in the malaria control experiments in Arkansas, public health training in Brazil, yellow fever work, and the work of the hospital ship in Philippine waters.

Walcott's Work in Brazil

The *Revista Medico-Cirurgica do Brazil* relates that at a recent meeting of the Academia Nacional de Medicina of Brazil, Dr. Allen Walcott was a guest and was proposed for corresponding member of the Academia. He is chief of the medical service of the great railway through the interior of Brazil, the Madeira e Mamoré R. R., and director of the Hospital de Candeleria. His work was described by Dr. A. Peixoto as, "since the Panama Canal, the most important and humanitarian work that has been done by modern hygiene," adding, "The success obtained by prophylaxis through this vast and rich zone has wiped the stain of unhealthfulness from tropical climates." He remarked that Dr. Walcott's own appearance, ruddy and robust, after nearly nine years' work in this field, is the best of testimony to the fact that he has transformed the country *da pestilencia á salubridade.* In describing the work of the medical department of the railroad, Dr. Walcott referred to some of the difficulties encountered, saying that malaria, beriberi and diphtheria ravaged the country. "It was indeed one vast cemetery. Those who come to Porto Velho today can have no conception of what conditions were when we started the work in those inhospitable lands, where the biped entered only at the sacrifice of his life." His observation soon convinced him that the beriberi of the Amazons was the same as the beriberi of Panama, and that its primordial cause is a one-sided diet. He promoted the cultivation of fruit trees, vegetables and a diversity of cereals, poultry and stock raising, etc., distributing seeds lavishly, and beriberi has now practically disappeared, as in this indirect way the populace were no longer restricted to the diet of *farinha de agua* alone, as formerly. Porto Velho is now a place where one can live with some comfort. One of the other speakers, Dr. T. Torres, said that in his town Manáos, "scarcely any vegetables or fruit are cultivated, poultry is imported from a long distance, and cabbages are imported from Lisbon to be sold at Manáos, while the population in the interior live exclusively on turtle meat and porridge (*farinha de agua*). The butcher shops sell only turtle meat, fish, game and the worst kind of beef. It is a most salutary example that has been set by the medical department of the Madeira e Mamoré R. R. at Porto Velho, fostering the cultivation of cereals, vegetables and fruits."

[Dr. Allen Moore Walcott is a graduate of the medical department of the University of California (1907), and served for a time in the Panama Zone.]

Report of United Fruit Company

In the annual report of the medical department of the United Fruit Company for 1918, attention is called to the loss of twenty-three of the staff of physicians during the year to enter the military service of the United States, and to the difficulty of securing suitable men to supply their places. Malaria, as heretofore, was the chief medical or sanitary problem. In the prophylaxis and treatment the forces were handicapped on account of the difficulty of procuring quinin in sufficient quantities, owing to the military requirements and regulations. The hospitals and dispensaries of the company treated 20,075 cases of malaria, with fifty deaths. There were forty-one cases of hemoglobinuria, with seven deaths. In the latter trouble one of the district superintendents suggested and used glucose in connection with physiologic sodium chlorid solution, with apparently good results, and the method will be employed in other districts and hospitals. *Balantidium coli* was found in two cases of dysentery in the Costa Rica division, in the persons of two laborers caring for pigs, in which as the host this parasite is found. In Cuba, among Haitian laborers, there was an epidemic of pneumonia which was attended by a high mortality. Seven cases of snakebite with two deaths, the snakes being the red viper and the water moccasin, were found in the Costa Rica division. Extensive sanitary work was continued in all the divisions, the work at Barrios, Guatemala division, being especially noteworthy. This was one of the most insanitary ports visited by the company's steamships. In connection with the International Railways of Central America it was cleaned up, and the condition with relation to mosquito infection is now greatly improved. One case of liver fluke (*Clonorchis sinensis*) was found in a Chinaman, and one case of mycetoma (Madura foot) and a number of cases of infestation with *Trichocephalus dispar* were reported. The company made an effort during the war to encourage the use of native foods, one instance being the use of boiled green banana pulp mixed with wheat flour dough in the making of bread, which effected a saving of from 25 to 30 per cent. of wheat. Physical examinations of all persons offering for employment resulted in the rejections of 7.8 per cent.

Eggs and Eggs

How to tell a bad egg is a question that has puzzled scientists, laymen and professional egg graders for many years, and it is evidently not yet a matter of mathematical accuracy. Any one can tell a bad egg after the shell is broken, but this is not the logical moment for the determination. The United States Department of Agriculture, through its Bureau of Chemistry, has published several interesting contributions on this subject (Eggs and Their Value as Food, Bull. 471, U. S. Dept. Agr. Bacteriological Study of Shell, Frozen and Desiccated Eggs, Bull. 158, Bureau of Chemistry. How to Candle Eggs, Bull. 565, U. S. Dept. Agr. Practical Suggestions for Preparation of Frozen and Dried Eggs, Circular 98, Bureau of Chemistry). The most recent study concerns accuracy in commercial grading of opened eggs. A previous bulletin of this department (A Bacteriological and Chemical Study of Commercial Eggs, Bull. 51, U. S. Dept. Agr.) described how eggs, good and bad, appear before the candle and out of the shell, and enumerated their respective chemical and bacteriologic characteristics. The most recent bulletin (Jenkins, M. K., and Hendrickson, Norman: Accuracy in Commercial Grading of Opened Eggs, Bull. 391, U. S. Dept. Agr.) is concerned with the grading of eggs by sight, smell and taste. It has been obseved that some eggs have a higher bacterial content than others. For instance, it has been found that 8.7 per cent. of eggs with sound shells contain bacteria, and that 18.6 per cent. of eggs with cracked shells and 30.7 per cent. of eggs with leaking shells are thus contaminated. In the same way the percentage of eggs containing bacteria is less in eggs with clean shells than in those with dirty shells; and as a corollary it was found that the percentage of eggs containing *Bacillus coli* is the same for clean, cracked eggs as for whole-shelled, dirty eggs. The physical condition of an egg indicates to a large extent its state of preservation. The white of a strictly fresh egg is stiff and the yolk stands up firmly; as the egg ages, the white becomes thinner, the yolk flatter and the vitellin membrane weaker. Therefore, when a stale egg is opened this membrane frequently ruptures, and when such an egg is dropped on a plate the contents of the yolk flow into and through the white. Such an egg is called a weak egg, although when it acquires an odor the laity would refer to it as a strong egg. Fertile eggs almost invariably contain weak yolks. It has been found that these eggs appear before the candle to have whole yolks; but on breaking, the yolk mixes freely with the white. It is believed that such eggs are suitable for baking and cooking if their odor is normal and the white not green when the egg is broken. If, however, the seepage of the yolk is so advanced that it extends entirely through the white, the egg should be discarded. When viewed before the candle, a strictly fresh egg will be found to have the yolk located slightly above the meridian and symmetrical with the long axis of the egg. It is indistinct in outline and moves sluggishly as the egg is turned. As an egg ages, the yolk becomes more opaque and may settle against the lowest part of the shell, finally adhering. Such eggs are frequently harborers of bacteria, although the settling of the yolk is not in itself an indication of the fact that the egg contains bacteria; on the other hand, they are sufficiently suspicious not to be included in food products. Most eggs containing bacteria may be recognized by the odor. A weak egg, the authors believe, if it is decomposed to such an extent that it has a muddy white or a whitish streak in the yolk, should be discarded for food purposes. The bulletins are well illustrated with colored plates which will be of great service to those interested in determining the quality of the hen's product.

Presence of Food Accessories in Urine, Bile and Saliva

Muckenfus conducted some experiments to determine the presence of food accessories (vitamins) in urine, bile and saliva, and records his results in the *Journal of the American Chemical Society*, October, 1918. Nine pigeons with acute symptoms of polyneuritis on a diet of polished rice were treated by mouth with fullers' earth activated with from 950 to 1,750 c.c. of fresh filtered ox bile. Eight of these showed improvement while observed, two for five and six days, respectively. Four pigeons with acute symptoms of polyneuritis were given fullers' earth activated with from 4,150 to 6,000 c.c. of fresh filtered human urine. All improved greatly, three of them for five, six and eight days, respectively, one of these having been observed for twelve days before suffering a second acute attack. Three pigeons with acute symptoms of polyneuritis were treated with different samples of fullers' earth that had been mixed with 2,950 and 3,250 c.c. of the bile filtrate from the activated earth. Two improved and one grew worse. One pigeon with acute symptoms was given fullers' earth treated with 15,000 c.c. of the urine filtrate from the activated earth, but continued to grow worse. Three pigeons with acute symptoms of polyneuritis improved after treatment with fullers' earth, activated with 400 to 1,325 c.c. of fresh filtered human saliva. Simple preventive tests with saliva were negative. Four "control" pigeons, which acquired the acute symptoms of polyneuritis on a diet of polished rice along with the others mentioned, were not treated. All grew worse, three dying within a day. The conclusions of Muckenfuss were that the experiments indicate that the antineuritic vitamin is probably present in comparatively small quantity in clean, fresh, filtered bile from the gallbladder of the ox. This food accessory is also present in fresh filtered human urine in traces, apparently.

Chemical Changes in Oysters During Preparation for Market

Edward E. Smith, junior chemist of the Bureau of Chemistry, United States Department of Agriculture, in Bulletin 740 gives the results of an investigation to determine the amounts of ammoniacal nitrogen, amino-acid nitrogen, moisture, total solids, ash and sodium chlorid present in oysters under the various conditions through which they pass in ordinary commercial practice in oyster houses, and to ascertain the effect of washing and soaking in both chemical composition and physical condition of the oysters. The findings, in part, are thus summarized: A marked loss of oyster solids and of ash constituents occurs on washing oysters with fresh water. Oysters covered with water but not agitated are not appreciably affected by osmosis except in relatively long periods of time. Solution proceeds slowly, but amounts to a large percentage of the solids originally present in the course of two or three days. If oysters are agitated in fresh water either mechanically or by a blast of air, a large increase in volume occurs in a short space of time, amounting to as much as 35 per cent. in thirty minutes, and to as much as 50 per cent. in ninety minutes, believed to be due to osmotic action. When washed in water of the same salinity as that in which they were grown, no increase in volume occurs and the loss of nutrients is slight. In the average of all the experiments the ratio of osmotic loss of solids to actual loss is approximately 2:1; for amino-acid nitrogen, all of which is soluble, but which goes into solution slowly, the ratio is approximately 1:1, and for ash-forming substance, which is composed largely of soluble inorganic compounds, the ratio is approximately 1:2.

Medicolegal

Validity of Provisions Concerning "Patent" Medicines

(E. Fougera & Co., Inc. v. City of New York et al. (N. Y.), 120 N. E. R. 642)

The Court of Appeals of New York says that Sections 116 and 117 of the sanitary code adopted by the board of health of the city of New York provided that there should be no sale of "patent," or proprietary, medicines in the city of New York unless the names of the ingredients of every such medicine to which the therapeutic effects claimed were attributed, and the names of all other ingredients, except such as were physiologically inactive, should be registered in the department of health, etc. The argument was made that the ordinance was an arbitrary exercise of the power of government. The court does not think so. Its purpose and effect were well within the limits of the police power. The purpose was the preservation of the public health and safety. The form of protection was publicity. There must be disclosure of the truth to responsible officials, who would prevent or punish the sale of fraudulent or noxious compounds. If that is not a legitimate public aim, the court is at a loss to know where one may be found. It was not important that the ordinance failed to compel disclosure to all the world. Laws are not invalid because they fall short of the maximum of attainable efficiency. Disclosure to all the world might make the protection more complete, but it would also make the hardship more severe. Something less, therefore, had been enacted. Disclosure was to be made to the health officers of the city, and to them only. If fraud or other wrong was discovered, then, and then only, exposure would result. "No man has a constitutional right to keep secret the composition of substances which he sells to the public as articles of food" (*State v. Aslesen,* 50 Minn. 5, 52 N. W. 220). If that is true of food, it is even more plainly true of drugs. A danger exists, and the only question is whether the means of correction are appropriate. The court cannot say that the means have no relation to the end. The public health is safeguarded by disclosure to public officers charged by law with its protection. The court is not called on to approve the wisdom of the ordinance. It stops when it satisfies itself that it has a reasonable relation to the end to be attained.

It was said that the effect of the ordinance was to compel the dealers in "patent" medicines to give evidence against themselves, in violation of the constitution of the state. But, accepting as accurate the stipulation that the admitted object of the defendants in the enactment was to secure information on which to base prosecutions for violations of law, if in their opinion the facts disclosed in accordance therewith should so warrant, the result would not be much changed. The sale of medicines is a business subject to governmental regulation. One who engaged in it was not compelled by this ordinance to expose himself to punishment for any offense already committed. He was simply notified of the conditions on which he might do business in the future. He made his own choice. To such a situation, the privilege against self-accusation has no just application.

It was said again that prosecution might follow if any statement in respect of the curative action of the drug was false, and that to permit this was to inflict punishment for mere error of opinion. The court has no doubt, however, that the word "false," as used in the ordinance, meant wilfully false or fraudulent. If this construction was adopted, the objection vanished.

Nor does the court agree with objections based on a supposed conflict between the ordinance and the federal constitution. It was true that there were some requirements of this ordinance which merely repeated prohibitions of the Food and Drugs Act. If prosecution was attempted for the violation of those requirements as a result of any transaction of interstate or foreign commerce, the question would have to be determined whether the state could thus add to the penalties of the federal law. But such provisions, if they were assumed to be invalid, were separable from the others. The dominant scheme of the ordinance was disclosure of ingredients. That disclosure may be compelled, and the failure to make it, punished, without trespassing on the field which has been occupied by Congress.

But there was one objection to the ordinance which the court thinks pointed to a real defect, though one that amendment might correct, that the ordinance did not except existing stores of merchandise in the hands of druggists or other dealers who did not know the ingredients and could not state them. In that the board of health exceeded the powers delegated to it.

Hospitals and Negligence of Incompetent Servants

(Mikota v. Sisters of Mercy et al. (Iowa), 168 N. W. R. 219)

The Supreme Court of Iowa holds that, in this action to recover for the death of a typhoid patient who jumped from a window of the defendant's hospital, a demurrer was rightly sustained to the plaintiff's petition, which alleged, among other things, that the officers, agents and attendants of the hospital, knowing that the patient was likely to be seized with delusions and delirium, received and placed him in a room on the fourth floor without bars on the windows, and left him there alone, or in charge of incompetent attendants and nurses, and that his death was due to their negligence. The court says that all charities must be administered through human instrumentalities; these are simply the agencies employed in the distribution of the charity, and he who accepts the charity through the instrumentalities employed cannot complain of the manner of distribution, though in it he receives a hurt. On the theory that the defendant was not liable for the negligence of its servants in this case, the court thinks the demurrer to the plaintiff's petition was rightly sustained. It might be contended, however, that the plaintiff had brought the case within the claimed exceptions to the general rule, and had alleged negligence on the part of the corporation itself. But a careful examination of the petition disclosed that in no place did it affirmatively appear that the injury complained of was caused or contributed to by any negligent act of the defendant, by not using reasonable care in the selection of its servants, or that the injury was due to negligence in the selection of servants, as differentiated from the negligence of the servants selected. When the injury is traceable to the negligence of the servant, there is no liability. If the case rested on the negligence of the defendant in the selection of incompetent servants, then it should appear affirmatively that the injury was traceable to such negligence. Even an incompetent servant may be negligent, and if the injury is traceable to such negligence, and not to the incompetency, then there is no liability under the rule. A fair interpretation of the language used leads the mind to the thought that liability was predicated, not on incompetency on the part of the servants employed, but on the negligent manner in which they, whether competent or incompetent, discharged the duty assigned. Even though the court grants the exception, it does not find the case brought within the exception, and the general rule must prevail.

License Revoked for Illegally Prescribing Drugs

(Knoop v. State Board of Health (R. I.), 103 Atl. R. 904)

The Supreme Court of Rhode Island, in this case arising on an appeal, affirms the finding of the state board of health revoking the certificate of appellant Knoop that authorized him to practice medicine and surgery in the state of Rhode Island, because of his having illegally prescribed morphin and cocain for drug addicts. The court says that he continued to treat a number of these addicts, when he knew, according to his own testimony, that they did not desire to be cured, that they were getting drugs from other sources in addition to the amount prescribed by him, and had secured prescriptions for additional amounts from him on their false statements that they had lost a part of their weekly supply. He admitted that a better way of securing a favorable result would have been to require his patients to come to his office at frequent intervals, thereby giving him the power to observe their conditions and control the size of the doses. His reason for not requiring this of his patients was that some of them were poor and that any such requirement would result in his losing his patients. But however well founded this fear may have been, it could hardly be urged seriously as a good reason for a failure to apply the method of treatment that was required. Moreover, before he went away for a vacation of a couple of weeks, in the fall of 1916, he filled out and signed a number of prescriptions for drugs, leaving a blank for the date in the month to be filled in when the prescripition was issued in his absence. These prescriptions were left with a female relative of his wife who was by arrangement to remain in his office and give the prescriptions to his patients if they called for them, and who then was to fill in the date on the prescription when delivered. This attendant had no medical training, and her only acquaintance with the patients was such as she may have acquired from having seen them in the office of the doctor at different times for a week or two prior to his departure.

That the appellant expected to cure his patients by such a course of procedure was incredible. That he did not expect to cure his patients was made clear by his own testimony, when he was recalled to the witness stand after other witnesses had testified in regard to his method of treatment. He then admitted that he did not expect to cure his patients, that the only practical way of effecting a cure would be by placing them under control in some institution, and that his object was to give his patients a sufficient supply of the drug to enable them to continue their usual occupations.

This particular testimony requires no extended comment. Such treatment for such an avowed purpose is illegal and unprofessional. One of the objects of the statute (Chapter 178 of the General Laws of 1909) is to prevent drug addicts from securing the desired drug and thereby enabling them to continue the drug habit. The legislature recognized the necessity of making some provision for these unfortunate people, and in a proper case the law permitted physicians to prescribe morphin, etc. Such treatment, however, must be in accordance with the recognized practice of medicine, the object of which, whenever it is possible, is to effect a cure.

Neither did the procedure followed by the appellant cure the patient, nor was it adapted to cure him. So long as the patient was able to procure his supply of the drug he would remain a drug addict. The treatment of the appellant was directed principally with the purpose of securing the fees which his patients paid him in order to secure the desired prescription, and the conclusion from the testimony was irresistible that whatever reductions were made in the amount of the drug prescribed were due more to a desire on his part to escape a prosecution for violation of the law than to any expectation on his part of effecting a cure of the patients or of securing for them any permanent benefit. The court is of the opinion that the appellant was guilty of grossly unprofessional conduct and of conduct making him an unfit person to practice medicine in Rhode Island.

Liability for Negligent Burning of New-Born Child

(Dalsgaard v. Meierding (Minn.), 168 N. W. R. 584)

The Supreme Court of Minnesota, in affirming a judgment for damages (amount not stated) in favor of a minor child named as plaintiff, calls the case not only an unfortunate, but a very unusual, one. The court says that the defendant on going to the Dalsgaard home, in response to a call, to attend Mrs. Dalsgaard in childbirth, found her sitting near the heater, and immediately put her to bed. He asked for a hot water bottle, and, being informed that they had none, he directed that some hot flatirons be wrapped, and these were placed at the patient's feet. Shortly thereafter the mother was delivered of the child named in this action as plaintiff. When the baby was born it did not breathe well, and to stimulate and start it breathing the defendant slapped it a few times, and then laid it back with its mother and placed a cover over it. Shortly the child began to cry vigorously. The mother remarked about the fact. The defendant raised the child up, but placed it back. The child continued to cry, and finally the defendant lifted the quilt and saw a flatiron against the baby's head. He removed the iron, and said to the parents: "It is no wonder the baby continues crying so long as the flatiron has become unwrapped and has slid against the baby's head." The right side of the face had been burned, the burn extending several inches above the ear and several inches below the lobe of the ear. The burn was deep, down to the skull. Later the upper rim of the ear sloughed off, and a part of the outer layer of the skull bone came out. The defendant testified that the mother moved about in the bed considerably during her labor, but remained practically quiet thereafter; that he paid no attention to how the irons were placed in the bed; that it was the continuance of the cry that caused him to raise the cover and discover the flatiron. It was claimed on the part of the plaintiff that, the defendant knowing of the presence of the hot flatirons in the bed, it was negligence on his part to have failed to look where he placed the child; that he should have considered that the motion of the mother during her labors was likely to interfere with the flatirons and cause them to become unwrapped and move toward the middle of the bed, where the child was placed, and that his duty as the physician in charge required of him to look so as to avoid the hot iron, and that his failure so to do was negligence for which he was liable. It was the claim of the defendant that the child was accidentally burned, without any fault or want of care on his part. It was also insisted on his behalf that the testimony in the case was insufficient to support the verdict. But this court is unable to say that the findings of the jury were not supported by the testimony. The trial court fully and fairly submitted the case to the jury, and their verdict was final. Physicians generally, as is their duty under circumstances as detailed in this case, look well to the surrounding conditions and to the welfare of their patients.

Development of Arteries of Human Lower Extremity. H. D. Senior. New York City.—p. 55.

Origin of Phagocytic Mononuclear Cells.—For studying the phagocytic activity of cells, McJunkin uses lampblack, which he claims has an advantage over intra vitam stains, since the reaction is almost immediate. By showing that cells which have ingested carbon (3 per cent. mononuclear ones) completely disappear from the peripheral circulation within twenty-four hours, the failure of those employing intra vitam stains to demonstrate any considerable number of phagocytic cells in the blood is explained. Another advantage of lampblack over intra vitam stains is that thin paraffin sections may be made of the tissue fixed in a way best calculated to bring out the histologic structure. In such sections the limitation of the ingested carbon to the endothelial cells and mononuclear leukocytes assumes the character of a specific reaction for cells of endothelial origin. McJunkin believes that the demonstration of mitoses in endothelial carbon-containing cells lining capillaries which are not lengthening is proof of the origin of phagocytic mononuclear blood cells from the endothelial cells of vessels. That the 5 per cent. of phagocytic mononuclear cells present in human blood consists entirely of endothelial leukocytes seems likely to McJunkin in view of the fact that there is positive proof of this origin and negative evidence showing that they are not of myeloblastic or lymphoblastic origin and that few phagocytic cells of any variety are present in normal extravascular tissue.

Practical Use of Wheatstone Stereoscope. H. C. Snook, New York.—p. 39.

Ventriculography.—Dandy has injected air into the cerebral ventricles at least twenty times. In some instances the injection has been repeated. The amount of air injected has varied from 40 to 300 c.c., the larger quantities in cases of internal hydrocephalus. Only once has there been any reaction, and in this case the injection (300 c.c.) was made forty-eight hours after the first stage of an operation for cerebellar tumor. All of the injections have been made in children varying from six months to 12 years of age. Invariably the lateral ventricle has been outlined sharply in the roentgenogram. In two instances the third ventricle and the foreamen of Monro were visible. In none, however, has the fourth ventricle of the aqueduct of Sylvius been observed. The practical value from pneumoventriculography is expected principally from the shadows of the lateral ventricles. Even in the few cases here reported ventriculography was a means of diagnosing internal hydrocephalus in the early states. Not only the existence of hydrocephalus but its degree and the amount of brain destruction are at once evident from the ventriculogram. Without a ventriculogram, Dandy says, the diagnosis of internal hydrocephalus in children is frequently guesswork; with the ventriculogram the diagnosis is absolute. Other intracranial conditions may be diagnosed in this manner.

Treatment of Syphilis at Out-Door Department, Toronto General Hospital. W. T. Williams, Toronto.—p. 139.

Fulminating Syphilid.—Gooken reports a case presenting secondary skin lesions, gumma of bone, gumma of lung, and hepatic-visceral involvement, simultaneously and within nine weeks of the appearance of the initial lesion and with the chancre still apparent. Along with this general acute infection the hirsute areas were spared, and both clinically and as far as the examination of the spinal fluid could show, the nervous system had been neglected by the disease. The infection was acquired from the wife, who herself offered no visible signs of the disease. It responded to antispecific treatment quite as readily as the milder manifestations of syphilis.

Coagulo Reaction in Syphilis.—A method is described by Toyama for determining the proper amount of calcium chlorid to be added to oxalate plasma for the preparation of cytozyme containing the smallest amount of thrombin. Of the different extracts of tissues used as antigen in the Wassermann reaction, Toyama says, the best for use as cytozyme in the coagulo reaction is a simple extract of human heart muscle prepared by extracting the tissue with alcohol for a period not exceeding four days.

Value of Laboratory Diagnosis in Neurosyphilis.—In 967 laboratory examinations made by Larkin and Cornwall of spinal fluids from a series of syphilitics with objective signs of nervous involvement, pathologic findings were present in 787, or 81 per cent. In view of the fact that approximately 20 per cent. of those suffering from neurosyphilis do not show pathologic fluids, they are of the impression that it is none too radical to assert that 30 to 40 per cent. of those infected with syphilis have foci in the central nervous system, and that these individuals are "potential candidates for one or other forms of neurosyphilis." From study of the laboratory findings of over 350 spinal fluids embracing some 1,500 examinations the authors are led to believe that there is a rather definite sequence in the appearance of pathologic changes in the spinal fluid. This sequence, though not invariable, is as follows: (1) increase in pressure, (2) increase in globulin, (3) abnormal colloidal gold curve, (4) pleocytosis, (5) positive Wassermann reaction. With certain limitations each of these factors has a value in differential diagnosis.

Syphilis and Its Relation to Infant Mortality.—The statistics reviewed by Jeans show that from 10 to 20 per cent. of adult males and about 10 per cent. of married women are syphilitic, and a minimum of 10 per cent. of marriages involve a syphilitic individual. Seventy-five per cent. of all the offspring in a syphilitic family are infected. In a syphilitic family 30 per cent. of the pregnancies terminate in death at or before the term, a waste three times greater than is found in nonsyphilitic families. Thirty per cent. of all living births in a syphilitic family die in infancy as compared to a normal rate of 15 per cent. in the same class. Probably 25 to 30 per cent. of clinically syphilitic infants die as a result of syphilis. But 17 per cent. of all the pregnancies in syphilitic families result in living nonsyphilitic children who survive the period of infancy. About 5 per cent. of the infant population is syphilitic. According to St. Louis vital statistics, 3.5 per cent. of all infant deaths are ascribed to syphilis.

Arsphenamin and Neo-Arsphenamin Plus Epinephrin.—The use of epinephrin in certain reactions following the intravenous injection of arsphenamin and neo-arsphenamin is discussed by Beeson. In a series of 500 intravenous injections of arsphenamin [using the diarsenol, arsenobenzol (Dermatological Research Laboratories, Philadelphia) and arsenobenzol (Billon brands)] Beeson has observed nitroid crises in approximately 3 per cent. Most of them occurred with diarsenol. He has seen a nitroid crisis appear with the first injection, so that the anaphylactic theory can not always be invoked. These crises have varied from a slight facial flushing with a feeling of fulness beneath the sternum or precordium to extreme redness of face, ears and neck with edema of the lips and tongue accompanied by marked air hunger and conjunctival injection. None of the patients exhibited syncope, but on three occasions marked prostration was complained of. All the injections were given in a dilution of 0.1 gram of arsphenamin to 25 c.c. of plain freshly bidistilled water. About seven or eight minutes was the average time consumed in giving a 0.6 gm. dose. Hence neither the concentration of the solution nor excessive rapidity of inflow were important factors. Beeson always adds 3 or 4 would seem that we have no unequivocal evidence regarding the occurrence of superfetation even in mammals other than man. Moreover, as far as man is concerned, the large amount of literature on the subject furnishes no cases more convincing than that of Calderini.[21] Most of them easily can be recognized, from the reports alone, as probable instances of twin pregnancy, in which one fetus died and then was retained until the birth of the other. Confusion is due largely to the fact that dead fetuses often are retained for a considerable period without showing very evident changes in form or gross structure. This seems to be due, in part at least, to retardation in the lytic processes in embryonic as compared with adult tissues, a phenomenon which has been referred to the slow postmortem development of acidity in embryonic tissues.

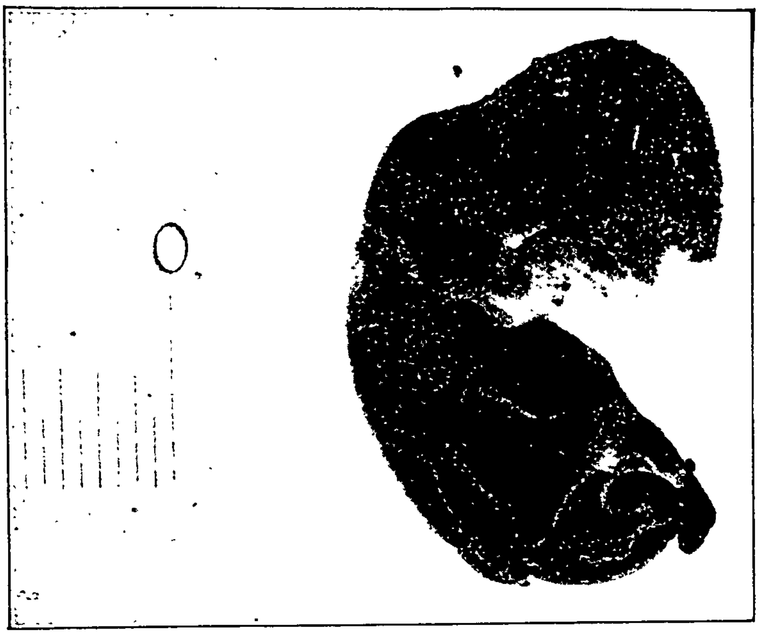

Fig. 8.—Pseudosuperfetus 1840 *b* from the Mall Embryological Collection, × 4; the maceration is very evident.

Since external form mainly is relied on as a criterion by the general practitioner, it is easy to see how misinterpretation of the facts arises, and it is significant that it is only the specialist who has come to doubt that supefetation ever occurs in human kind. This assumes, however, that by superfetation is meant the partly simultaneous intra-uterine development of two or more fetuses derived from ova liberated by independent ovulations separated from each other by a considerable period of time; or, in brief, the superposition of one pregnancy on another.

INSTANCES OF TWIN PREGNANCY

Since most reports on superfetation concern fetuses in the later months of pregnancy, it occurred to me that a representation of certain instances of twin pregnancy from the earlier months of pregnancy might be of special interest because such specimens could more easily and rightly be taken for examples of true superfetation. In the cases under consideration, one fetus evidently died some time before the abortion of both, a circumstance that resulted in considerable differences in age and form between the two. An examination of the accompanying cases will make it clear that all the instances here reported easily could be included among the alleged instances of superfetation found in the literature without doing the least violence to that literature. More than that, the instances here reported would form fine examples among such cases.

The youngest specimen contained in the Mall collection which came to my attention, and which might be regarded as one of superfetation, is No. 587, donated by Dr. F. A. Conradi of Baltimore. The cavity of the larger chorionic vesicle in the fresh specimen measured 32 by 23 by 23 mm., and that of the smaller about 6 by 6 by 9 mm. The latter was empty but the former contained a cylindric embryo 7 mm. long which Mall found greatly dissociated with a practically solid brain and only a remnant of the intestine. The amnion was present, and as shown in Figure 4, both vesicles formed a single mass which was covered by infiltrated decidua. That these chorionic vesicles both once contained an embryo, no embryologist will doubt. It is evident also that both were retained for some time after life and growth had ceased. The gross and histologic appearance of the entire specimen alone is sufficient proof of this. Although the smaller chorionic vesicle was incorporated in the margin of the larger, its death did not lead to its abortion or to that of the surviving twin. Yet the smaller of these twins undoubtedly died a considerable period before the larger. This is indicated also by an examination of the specimens and by the presence of decidua between the villi belonging to the respective vesicles at a point where they come in closest contact. An examination of this area shows that the ovum giving rise to the smaller conceptus was embedded independently, although undoubtedly also contemporaneously with the larger. Hence this specimen cannot be rightly regarded as one of superfetation.

The next specimens of twin pregnancy which might be regarded as a case of superfetation are Nos. 788 *a* and *b*, donated to the Mall collection by my friend, Dr. Anfin Egdahl. These twin chorionic vesicles, which were almost of the same size, measured 60 by 45 by 40 and 60 by 55 by 40 mm., respectively. Although of approximately the same size, the former contained a stunted embryo 17 mm. long, but the latter a nodular one only 3 mm. long. The differences in size and in the character of the two embryos are so marked that they prompted the late Professor Mall to make special inquiry of Dr. Egdahl as to whether these chorionic

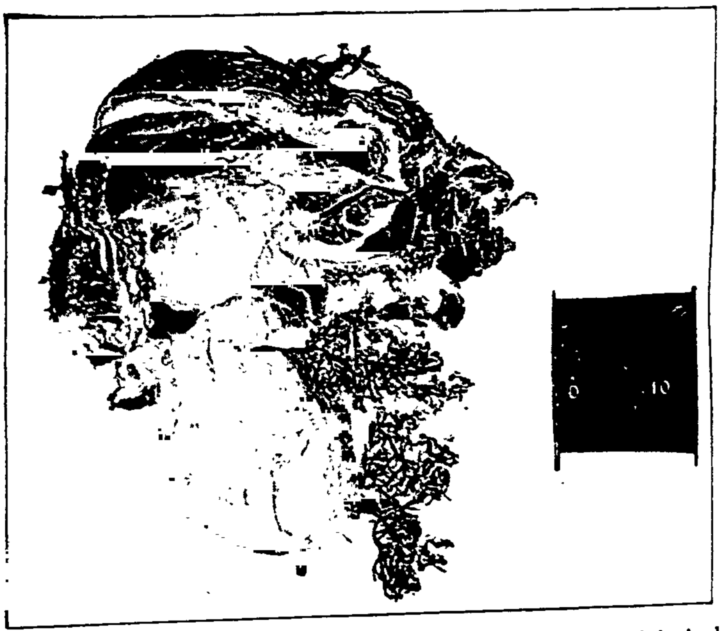

Fig. 9.—Everted chorionic vesicle of Fetus 1840 *a* below, and incised vesicle of 1840 *b* above, both forming a single mass.

---

[21] Calderini, G.: Ueber einen Fall von Superfötation, Gynäk. Rundschau 3, 1909.

vesicles really were obtained from the same patient, as reported. This inquiry Dr. Egdahl was able to answer promptly and positively in the affirmative. Here we are again dealing with a case of twin pregnancy in spite of the fact that the size of the embryos might seem to indicate that we really have a case of superfetation under consideration. But that the case is not such is shown also by the fact that the chorionic vesicles practically are of the same size. The smaller abortus with a partially inverted chorionic vesicle containing the better preserved of the twins is shown in Figure 5. Figure 6 shows the appearance of the larger abortus, which contained the smaller nodular embryo only 3 mm. long. The latter is seen at a midpoint near the upper third of the illustration. Both illustrations are practically of natural size. The larger fetus, the external form of which was fairly preserved, had an approximate age of about 48 days, as estimated by the Streeter[22] curve. Mall noted that the organs could all be outlined, but that they were dissociated and that the mandibular region had fused with the skin of the thorax. The small nodule, which represents the only remnant of the embryo belonging to the larger chorionic vesicle, contains a large cavity with thick, fibrous walls. Nothing but epidermis and a remnant of the nervous system could be recognized.

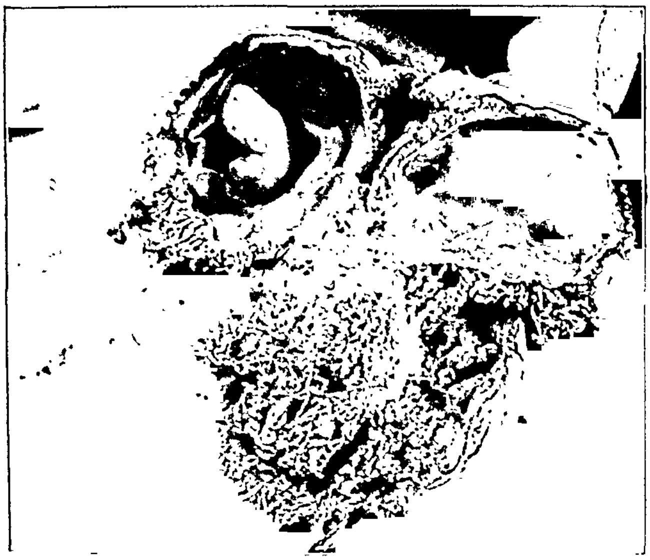

Fig. 10.—The same specimen as in Figure 9, showing the opposite side with the smaller fetus in loco.

A far more convincing instance of apparent superfetation was found in a specimen of twins donated by my classmate, Dr. Jane Ross of New York. The fetuses, Nos. 1840 *a* and *b*, contained in this abortus are shown in Figures 7 and 8. The larger measured 31 mm., but the smaller only 15 mm., indicating respective ages of 63 and 45 days. The chorionic vesicles belonging to these twins, which formed a single mass, are shown in Figures 9 and 10. The incised vesicle containing the smaller fetus is shown in Figure 10, and the larger vesicle, which is somewhat inverted, is shown in Figure 9. Since the latter had been opened and the larger fetus exposed, I at first overlooked the smaller fetus and found it only at a subsequent examination made for the purpose of determining the cause for the peculiar consistency and appearance of this portion of the abortus. The condition of the smaller fetus, which is well revealed in Figure 8 under a magnification of 4 diameters, is abundant evidence of the fact that it died a considerable period of time before the abortion occurred. This interval must have been several weeks. This specimen also nicely illustrates the fact that the death of one fetus does not necessarily result in the immediate abortion of it and its vesicle or of the other chorionic vesicle, as is sometimes still assumed.

Through the generosity of Dr. Gustetter I am also enabled to present reproductions of the fetuses spoken of in his article. They are shown in Figures 11 and 12, and from these illustrations it is clear that the smaller of the two fetuses probably stopped growth at about the sixth week. After this it became macerated and finally disintegrated, while the larger continued to grow, as in case of the specimen from Dr. Ross. The larger of these fetuses is practically normal in appearance except for the postpartum shriveling. It is approximately 100 days old.

Other specimens in the Mall collection, such as 2036 *a* and *b*, might well be included here, for one fetus was grouped as normal and the other as macerated. Indeed, it is a not very rare occurrence to find that the fetuses in a twin pregnancy had to be placed in different groups by Mall and his associates at the Carnegie laboratory. However, this was not done because such specimens were regarded as instances of superfetation, but because the fetuses, although of the same age, differed in form and appearance. It is interesting that Saniter[23] also reported a case of two unequally developed conceptuses from a tube. These conceptuses had separate chorionic vesicles, one of which was implanted in the isthmus and the other near the fimbria. The

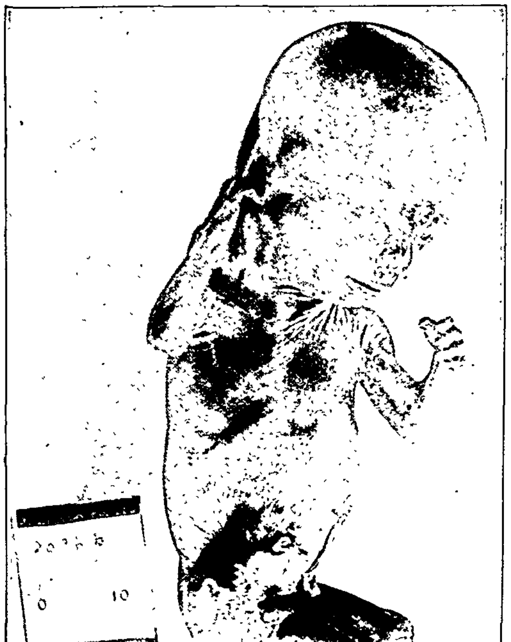

Fig. 11.—Pseudosuperfetus 2036 *b* from the Mall Embryological Collection.

---

[22] Streeter: Unpublished data.

[23] Saniter: Ber. d. Ges. f. Geb. u. Gynäk., Berlin Centralbl. f. Gynäk. 27, 1903.

former was said to be only of the third to the fourth week, while the latter contained a fetus 4 cm. long. Both chorionic vesicles were said to have ruptured freshly. In commenting on this case of Saniter's, Werth[24] says that he regards the question as to whether it was a case of superfetation or merely one of twin pregnancy an open one.

It may be recalled that the occurrence of fetus papyraceus in cases of twin pregnancy also has been attributed in the past to superfetation. Moreover, as stated above, intra-uterine death of one or more fetuses belonging to the same litter is relatively common in some mammals. However, since Jenkinson[25] stated that the allantois and its blood vessels and also the syncytium are regularly retained at birth in some marsupials, to be absorbed later through the activity of maternal leukocytes, it is evident that one must use caution in judging on the basis of experience in other mammals, especially the lower ones. In some of these the conditions apparently are quite different from those encountered in man, and Strahl and Henneberg[14] pointed out that in the mole the entire placenta and membranes, as Hubrecht stated, often are retained for a month after parturition. No one would assert, to be sure, that the human uterus shows the same tolerance or the same resorptive power, yet the daily experience of physicians as well as the literature in obstetrics and gynecology is replete with instances of retention of the membranes or the entire conceptus long after the death of the fetus. Although the presence of a surviving conceptus in multiple pregnancy materially alters the intra-uterine conditions, it also would seem to predispose to retention rather than to hasten the expulsion of the dead mate. That is, the survival of one twin, especially in the earlier stages of development, may depress rather than enhance the factors that lead to abortion.

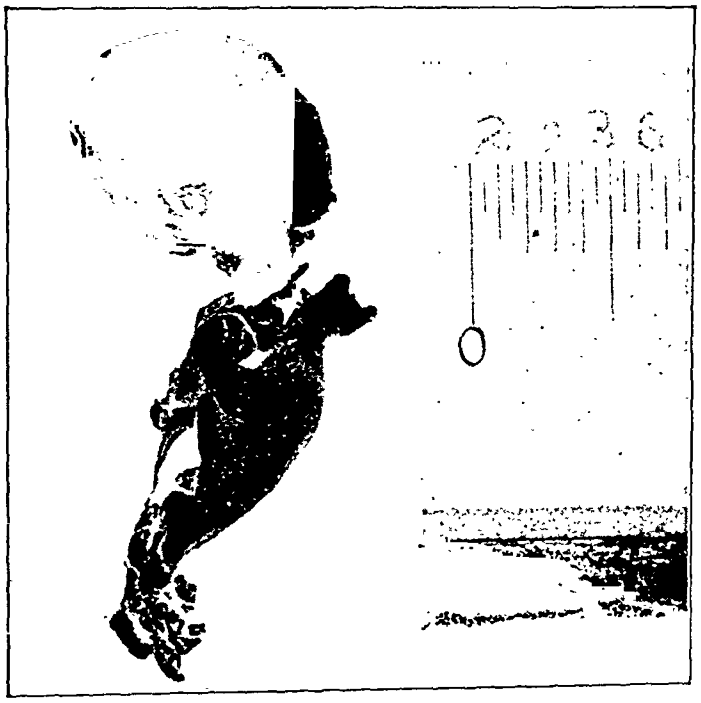

Fig. 12.—Similar specimen, No. 2036 *a*, from the Mall Embryological Collection; × 3.

The impulses arising from the presence of the dead fetus may be counterbalanced or offset for a time, at least, by the presence of the living fetus, and thus tend to prolong the status quo. This would be the case particularly, whenever, as in the specimen donated by Dr. Ross, the two chorionic vesicles are fused into a single mass; for then the portion belonging to the dead fetus, even if it forms one half of the combined mass at first, soon is outstripped in size by the surviving vesicle, which, in the absence of infection, may continue to grow quite undisturbed, for some time at least; and even in the case of infection of the dead vesicle, prompt invasion of the living does not necessarily occur. Aside from clinical experience, this was indicated also by the experiments of Maffuci[26] on incubating eggs and on pregnant rabbits and guinea-pigs. The apparent resistance of the young fetus to syphilis, the characteristic lesions of which have not as yet been successfully demonstrated in fetuses much before the first half of pregnancy, also would seem to point in the same direction.

CONCLUSION

From these considerations it would seem to follow that especially favorable conditions for the production of gross differences would seem to exist in some cases of twin pregnancy. Hence it need not surprise us that these differences have been largely responsible for the quite general belief in the occurrence of superfetation in women. But at present it remains merely a possibility; for the evidence on which this belief rests is wholly inadequate, and it is interesting to recall that in the past, fetus papyracei also have been regarded as examples of superfetation as illustrated by the specimens reported by Fasola.[27]

I gladly acknowledge my indebtedness to Prof. George S. Huntington for the cat fetus shown in Figure 2 and to Profs. Mary Harman and Albert Kunz and the Wistar Institute and the Modern Hospital Publishing Company for permission to reproduce illustrations from their publications.

EXPERIMENTAL MOSQUITO CONTROL IN RICEFIELDS

J. C. GEIGER, M.D.
Assistant Epidemiologist, U. S. Public Health Service
AND
W. C. PURDY, M.S.
Plankton Expert, U. S. Public Health Service
LITTLE ROCK, ARK.

During 1918, observations near Lonoke, Ark., extending over the entire rice-growing season from June to September inclusive, indicated the general prevalence of the following conditions:

1. *Anopheles* breeds within the rice fields in about equal quantities with *Culex*, both being found in moderate abundance.
2. Breeding occurs with fair uniformity over the entire field, with slight preference shown for the more open water along levees.
3. Breeding of both *Anopheles* and *Culex* begins ten days or two weeks after fields are flooded, and continues, with some variations, until late in September, when it diminishes gradually.
4. Top-minnows in the fields are to be found usually along the levees or at the water inlet, but rarely are they seen in midfield.

5. Predatory insect larvae, principally *Hydrophilus, Dytiscus* and certain *Odonata* (damsel-flies), are usually abundant enough to constitute a probable factor in the natural destruction of mosquito larvae.

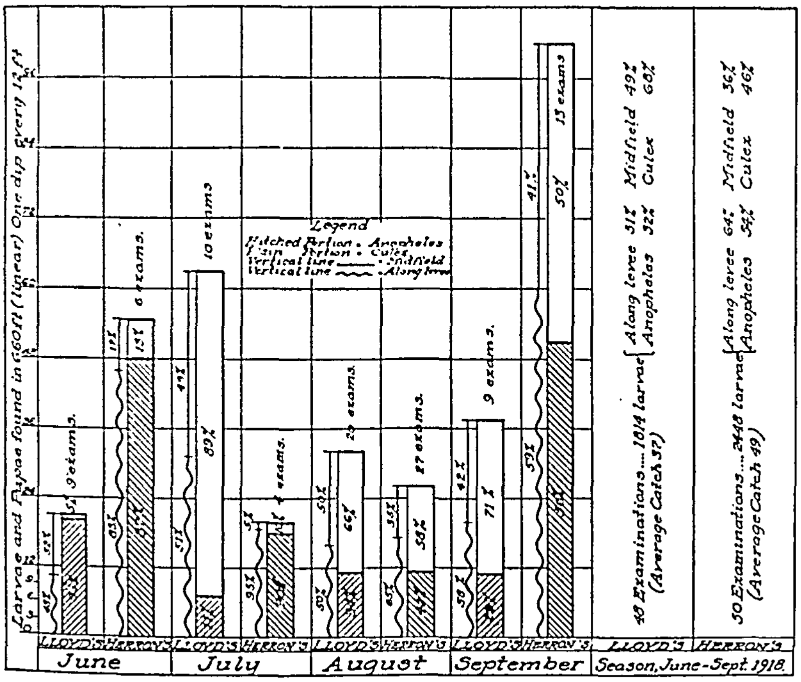

Chart 1.—Average larvae content, per examination, of rice plots while unaffected by remedial measures, by months. Each examination covers twenty-seven composite dips along the levee (330 ft.) plus twenty-seven dips in midfield, over like distance.

The foregoing observations are based on standardized and comparable examinations, forty-eight at one farm and fifty at another some miles distant. Essentially similar results were obtained at each farm, excepting that *Anopheles* outnumbered *Culex* at one farm, while the reverse was true at the other place. Also, at the first farm, total larval production was greater by about 29 per cent.

These examinations were conducted on ten small fields of one acre each, isolated by levees, but forming a part of a larger rice field, and being subject to the same treatment as regards seeding, watering, etc., as was this larger field. Frequent examinations were made of this large field, and of other near-by ricefields, and it was found that essentially the same conditions as to kind, number and distribution of mosquito larvae, and presence of fish and insect larvae prevailed here as were found throughout the season in the small fields under constant observation.

In view of the interest and great practical importance attached to *Anopheles* as a factor in the dissemination of malaria, it became desirable to know whether any practical application of remedial measures were possible in the ricefields, to the end that these vast, newly formed breeding areas might yield the minimum of malarial mosquitoes without interference meantime with the maximum yield of rice.

In considering any measures to reduce breeding of mosquitoes in ricefields, a vital factor is the presence of the rice itself. It is obvious that a ricefield cannot be drained in order to abolish mosquito breeding, nor can the water be treated with any larvicidal material that would endanger the rice crop. These restrictions with respect to treatment increase the difficulty of the problem in hand.

A further matter of importance is the item of expense involved. Any considerable addition to the present heavy expense of raising a crop would render a given remedy impossible of practical application by the rice farmers.

Keeping in mind the important factors of effective larvicidal action, no injury to rice crop, and cheapness and ease of application, investigations were undertaken to determine the practicability of employing certain measures to control mosquito breeding in the ricefields near Lonoke, Ark.

At each of two rice farms, five one-acre plots were used for this study. One plot at each place was reserved as control, no remedial measures of any kind being applied. On the remaining four plots at each farm, (1) fuel oil (technically known as "gas oil"), (2) "two-plus-one" oil mixture, (3) top-minnows (*Gambusia*) and (4) intermittent flooding, were the respective control measures applied. All five plots at each place bore the usual rice crop.

TECHNIC

1. The deeper water along the levee was examined by taking a composite dipperful every 12 feet for the length of the levee, or 330 feet, the dipper being filled by three or four partial dips taken while traversing the distance of 12 feet. After the number of larvae and pupae had been recorded, these were replaced in the field.

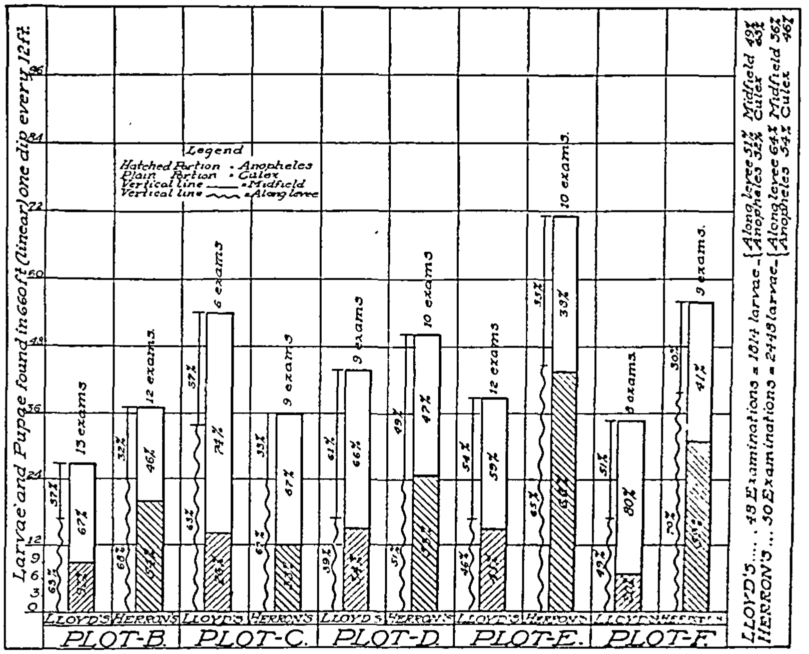

Chart 2.—Average larvae content, by plots, per examination (during the entire season), of the five plots while unaffected by remedial measures.

2. This procedure was repeated for a like distance, 330 feet, in midfield.

3. The total number of larvae and pupae thus found along levee and in midfield was regarded as the "catch."

4. Presence of other forms of life, both plant and animal, was noted and recorded. Beginning with August, definite count was kept of larvae of beetles, damsel-flies, etc.

Thus one examination of a plot included inspection of about *fifty-four* composite dipperfuls taken along levee and in midfield. together with observations as to the presence of aquatic insects and their larvae, also as to fish and crayfish, algae, and other aquatic plants, especially *Chara*.

In Table 1 is summarized the seasonal history of the several plots at Lloyd's farm. The forty-eight examinations here tabulated were taken at such times as the plots concerned were not showing the effects of remedial measures. The data are therefore fairly representative of conditions as they exist in the average ricefield.

* Six catches only. † Two catches only. ‡ Five catches only. § Four catches only.

In Table 2 the same data are grouped by plots, to facilitate comparative study of the several units concerned.

In Table 3 will be found the seasonal history shown by fifty examinations of the plots at the Herron farm, and in Table 4 the same data arranged by plots, for comparative study.

In Chart 1 is shown graphically the average catch at each farm during the several months of the rice season. The totals; the proportion of *Anopheles* to *Culex;* and the relative catch along levees and in midfield, are also shown. In Chart 2 the same data are arranged by plots. Charts 3 and 4 show seasonal fluctuations of larvae in all plots, and the effects of remedial measures used.

FUEL OIL ON LLOYD'S FARM

Application.—Rice was from 18 to 20 inches high, and in the stooling stage, when fuel oil was applied by a drip-can placed 5 feet above the water surface at the entrance gate. Oil at the rate of 30 gallons per acre was delivered to the water as it passed through the gate to flood the plot.

Distribution.—The spread of oil film was unsatisfactory. Continuously opposed in its progress by the rice stalks, most of the oil remained for several days puddled to some extent *within 20* feet of the drip, and only after a week or more was an oil film perceptible 150 feet away.

Effects.—1. On Rice: Wherever much oil came in contact with rice, the stalks were "climbed" and discolored, and some were killed. No injurious effects were observed when only a thin film of oil was present.

2. On Mosquito Larvae: Larvae were killed wherever the oil film penetrated. Results were immediate near the drip, but were delayed elsewhere, because oil did not spread. Near the drip the oil apparently remained effective for about four weeks.

FUEL OIL ON HERRON'S FARM

Application.—The rice was about 3 feet high, and was beginning to blossom. The oil was applied by means of broadcasting oil-saturated sawdust, one bushel of sawdust absorbing about 3 gallons of oil. This procedure was for a twofold purpose: (1) to secure uniform distribution of the oil among the rice, and (2) so to apply this oil to the plot that the rice crop would not be injured thereby. The use of 26 gallons per acre, applied in this way, gave a uniform but thin film over the entire plot.

Effects.—1. On Rice: There were no injurious effects. The oil did not puddle, or climb the rice stalks.

2. On Larvae: The larvicidal action was immediate. Examination two days after application showed reduction of 85 per cent., and four days after application 74 per cent. reduction was noted. In eight days, the presence of minute larvae in large numbers indicated resumption of breeding.

In a second application nearly one month after the first one, 35 gallons of oil were applied by use of saturated sawdust. The results were highly satisfactory. The rice was not injured, and examinations of the plot four days, one week and two weeks after application of the oil gave wholly negative results as to the presence of larvae.

TWO-PLUS-ONE OIL MIXTURE ON LLOYD'S FARM

Application.—The rice was from 18 to 20 inches high and in the stooling stage. The oil (two parts of kerosene plus one part of black oil) was applied by a drip-can placed 5 feet above the water at the entrance gate. It was intended to apply 30 gallons per acre, but persistent clogging of the drip and puddling of oil in the rice made this impossible.

Distribution.—The spread of oil was very poor. Most of the oil apparently remained hopelessly puddled about 10 to 15 feet around the drip. Several days of very hot weather seemed to help matters, but the better distribution may have been due to the separating of the lighter kerosene from the heavy black oil in the mixture.

Effects.—1. On Rice: A few square yards of rice about the drip were killed, but no other damage was apparent. The rice stalks were not climbed or discolored.

* This table includes the three October catches at Herron's which are not included in Charts 1 and 2.
† Twelve examinations. ‡ Seven examinations. § Nine examinations. ¶ Eight examinations.

2. On Larvae: These were killed wherever the oil film extended. After six days, larvicidal action was observed 50 feet away from the drip. Limited larvicidal action was indicated along the levee from 60 to 80 feet away, eight days after application. The results were not uniform or satisfactory, probably owing chiefly to poor distribution of the oil.

TWO-PLUS-ONE OIL MIXTURE ON HERRON'S FARM

Application.—A thick stand of rice was about 3 feet high and beginning to blossom, when 27 gallons of two-plus-one oil mixture were applied by means of saturated sawdust. The resulting oil film was quite uniform.

Effects.—1. On Rice: No damage resulted.

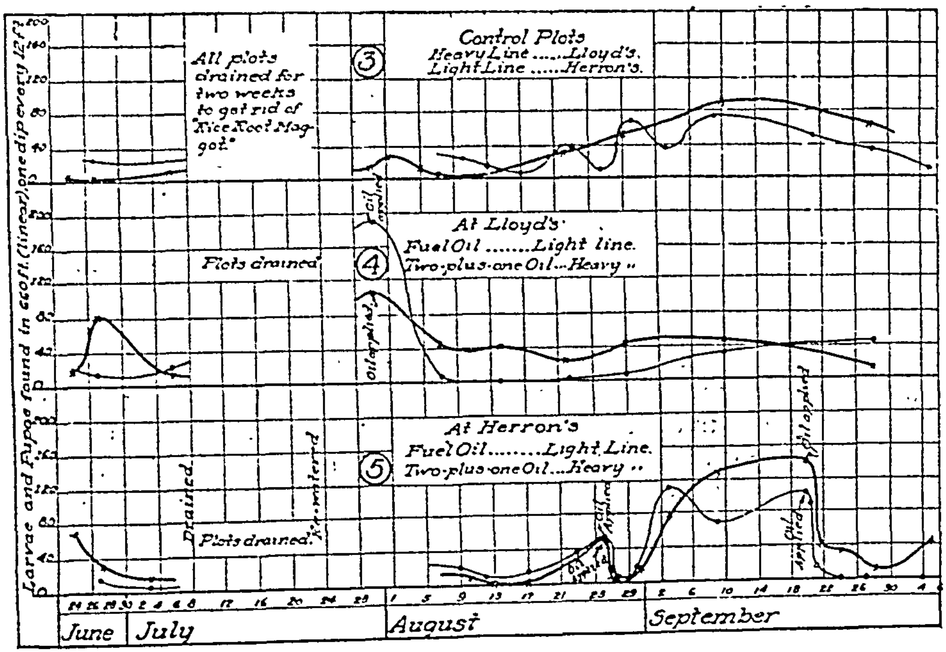
2. On Larvae: Larvicidal action was immediate and fairly satisfactory. The presence of very small larvae one week later indicated breeding but not production of sanitary importance. Very probably the amount of oil used was not sufficient for the best results.

A second trial of this oil mixture was made several weeks later. In this case "fuel oil" was substituted for the more expensive kerosene in the mixture. Thirty-three gallons were applied to one acre of rice, which was very thick and beginning to ripen. Distribution was effected by oil-soaked sawdust.

No damage resulted to the rice. Larvae were quickly and heavily reduced, but were not quite eliminated. Examination one week after application showed a reduction of larvae by 93 per cent. In two weeks, however, breeding had begun again, as shown by moderate numbers of very young larvae. This presence of very young larvae cannot be considered to be of sanitary importance.

TOP-MINNOWS (GAMBUSIA) ON LLOYD'S FARM

The rice was from 18 to 20 inches high and in the stooling stage when 1,400 top-minnows, obtained locally, were uniformly distributed by placing them at various points in the plot.



Charts 3, 4 and 5.—Larval history of plots showing effects of remedial measures (fuel oil and two-plus-one oil).

Distribution.—Although they were placed all over the plot, subsequent examinations indicated that practically all the minnows were along the levees (where the water was deeper) and especially at the entrance when the water was flowing on plot. They were rarely seen in midfield.

Effects.—Mosquito larvae showed a reduction of about 70 per cent. in one week. Subsequent weekly examinations disclosed the continuance of approximately these conditions for eight weeks, when examinations ceased.

TOP-MINNOWS ON HERRON'S FARM

The rice was about 3 feet high and partly in blossom when 800 top-minnows were distributed in the plot.

Distribution.—Subsequent observations revealed that these fish showed decided preference for flowing water near the gate, and for the deeper water along the levees. Only an occasional minnow was seen in midfield.

Effects.—The initial content of larvae was reduced by about 35 per cent. in two days, but in one week there was an actual increase of 85 per cent. This increased larval content continued with little change for nearly five weeks. However, most of the larvae that constituted the increase were so small that the fish could find them with difficulty or not at all. It seems evident that the efficiency of the fish cannot be justly measured by the relative abundance of these very small larvae, but that the practical absence of large larvae and of pupae is a truer indication.

INTERMITTENT FLOODING OF LLOYD'S FARM

A thick stand of rice about 20 inches high was on plot when water was first withdrawn in order to get rid of mosquito larvae. The water was drained into a large ricefield adjoining. The plot was reflooded within a week.

Effects.—1. On Rice: No effects were apparent.

2. On Larvae: Practically all larvae were removed as a natural result of draining the water into the adjoining field. It is not only probable that few were actually killed, but that, on the contrary, they continued to develop in the next field.

A small amount of water remained along the levees and in depressions of the plot. The common level of most of the land in the ricefields makes perfect draining impossible. A few larvae were to be found in these remaining puddles.

Eleven days after this plot was reflooded, larvae were again found in moderate abundance. This condition obtained until the plot was drained a second time, four or five weeks later.

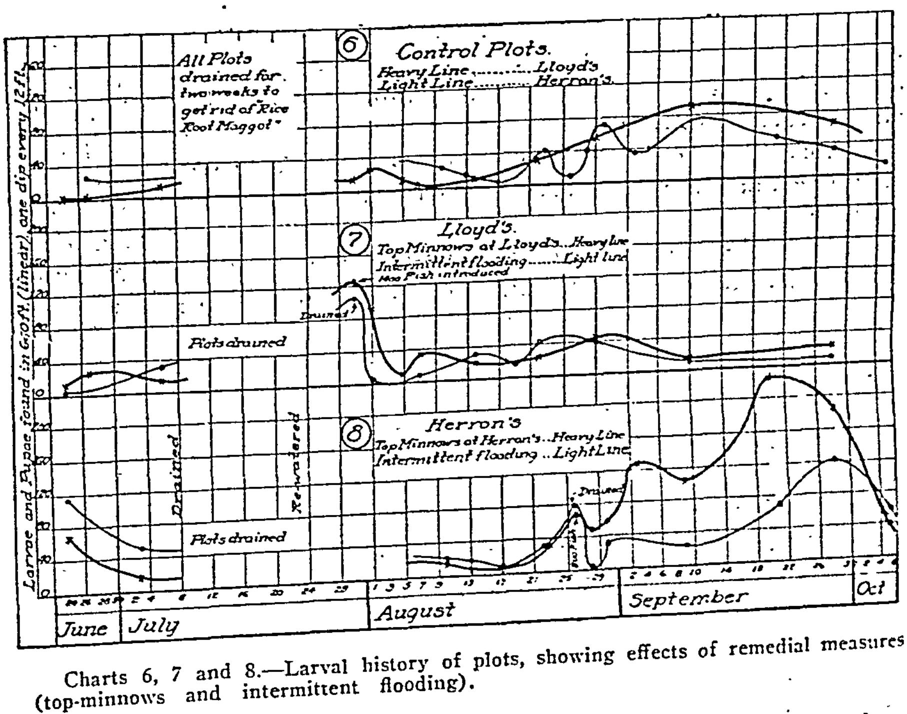
The second draining removed nearly all the larvae. The plot was rewatered within a week. No examination was made for two weeks or more, when larvae were again present, but not in large numbers.

INTERMITTENT FLOODING OF HERRON'S FARM

The rice was beginning to blossom when the water was drained into the large ricefield adjoining. A small amount of water remained in depressions in the plot. Water was again turned in after one week.

Effects.—1. On Rice: No effects were apparent.

2. On Larvae: Most of the larvae were removed, but the small amount of remaining water showed moderate numbers of larvae four days after draining.



Charts 6, 7 and 8.—Larval history of plots, showing effects of remedial measures (top-minnows and intermittent flooding).

Six days after reflooding the plot, a number of large larvae were found. These evidently had remained over, in the small puddles that could not be completely drained. Two and one-half weeks after reflooding, larvae were present in quantity. The plot was not drained, however, because the rice was "heading," and lack of abundant water at such a time would probably have resulted in serious injury to the rice.

The larval history of the control plots is shown in Charts 3 and 6 for comparison with the like history of other plots in which remedial measures were used (Charts 4, 5, 7 and 8). Examinations of these controls were made at the same time and in the same manner as of the other plots.

Unfortunately, conditions were not quite normal in the control plot at Lloyd's, owing to the presence of a heavy growth of filamentous algae during August and the first part of September which covered a considerable portion of the water surface and thus greatly reduced the surface area available for mosquito breeding. To this condition (which was not present in other plots) is probably due the relatively low content of larvae.

The control plot at Herron's was unfortunate also in the latter part of the season, when hogs broke the levee and caused the loss of water which could not be replaced at the time. To this the low count in September is evidently due. For some reason not apparent, other counts in this control plot were low, and showed heavy fluctuations (Chart 3).

SUMMARY

1. The average larval catch (in about fifty-four composite dipperfuls) at Lloyd's was thirty-seven, and at Herron's it was forty-nine (Chart 1).

2. *Anopheles* predominated slightly during the season in the Herron plots, forming 54 per cent. of the season's catch. *Culex* predominated at Lloyd's, forming 68 per cent. of the total catch of the season (Charts 1 and 2).

3. Breeding along levees, forming 64 per cent. of the total, exceeded that in midfield in the Herron plots, but at Lloyd's, breeding was about equal in the two locations (Charts 1 and 2).

4. *Anopheles* larvae were relatively most abundant in June and July. In the latter month, *Culex* gained ascendency in the Lloyd plots and retained the lead the entire season (Chart 1).

5. Insect larvae are relatively abundant, being nearly as numerous, in some cases, as are mosquito larvae (Tables 1 to 4).

6. Both the fuel oil and the two-plus-one oil mixture failed to spread through rice when applied by drip-can, but uniform distribution with satisfactory larvicidal action without harm to rice was secured by the use of oil-saturated sawdust.

7. Plot E at Lloyd's, containing 1,400 top-minnows, shows immediate reduction of larvae, with satisfactory duration of this good result. Plot E at Herron's, with 800 top-minnows, shows poor results apparently, but most of the larvae found were very small and may have escaped the fish only temporarily (Charts 7 and 8). In many of these experiments the practical absence of pupae and any larvae except small ones must be looked on as indicating effective control, and not in the light of production in public health quantities.

In the same plot, insect larvae were so few (relatively) as to indicate probable depredations by fish.

8. During the season, 129 examinations were made. These reveal the larval history for the entire season and are plotted in Charts 3 to 8, inclusive. Of these examinations, ninety-eight were taken when plots showed no distinct effects of remedial measures applied. Results are shown in Charts 1 and 2.

CONCLUSIONS

1. Intermittent flooding as a control measure is probably not feasible, owing to the additional cost of water and to the usual impossibility of the transferal of larvae beyond flight distance.

2. The preference shown by top-feeding minnows for the deeper, flowing water along levees and their evident avoidance of the midfield make them a doubtful control measure. Nevertheless, they have demonstrated under experimental conditions what has been observed under field conditions in Arkansas, Louisiana and California, that their presence means a considerable reduction in mosquito larvae.

Roadside ditches containing top-feeding minnows usually show larvae very few or absent. The ditch, however, is not comparable with the ricefield as an environment because of great differences in area, in abundance of obstructions for fish, and in amount of light.

3. Oil of the various varieties used in these experiments by drip-can methods proved a failure. The results obtained when used with sawdust are such that they offer future hopes for ultimate mosquito control in ricefields within reasonable flight distance of communities, and a corresponding reduction of incidence of malaria.

THE RELIABILITY OF THE NYSTAGMUS TEST *

LEWIS FISHER, M.D. (Philadelphia)
Major, M. C., U. S. Army
AND
HAROLD L. BABCOCK, M.D. (Boston)
Captain, M. C., U. S. Army
MINEOLA, L. I., N. Y.

Bárány wrote in 1912 that in Vienna no examination of patients with nervous symptoms was considered complete without a careful examination of the vestibular apparatus. Even then the profession abroad had come to realize that a complete ear examination is a great aid in general medical diagnosis. In the United States we have similarly come to realize the usefulness of ear studies, and at present otologists are being called on for examinations of the vestibular mechanism. The usual method of examination of this mechanism is to set the lymph within the labyrinth in motion by means of turning or douching, and then measuring the responses obtained. These responses are nystagmus and vertigo. Examinations of a very large number of individuals—more than a hundred thousand—have shown that in normal persons the average duration of the after-turning nystagmus is 24 seconds. This duration of nystagmus then came to be considered as one of the expressions of the normality of the vestibular mechanism. With this standard as a basis, examinations were conducted in pathologic clinical cases for a number of years, and whenever the nystagmus varied considerably from the normal 24, the vestibular mechanism was considered proportionately affected. Deductions, in the matter of diagnosis and location of intracranial lesions, based on this standard, proved remarkably accurate, as verified by subsequent operations or necropsies.

When we entered the war it became obvious that the army would require a large number of aviators.

---

* From the Medical Research Laboratory.

Realizing the arduous and unusual duties demanded of air pilots, every means was naturally adopted to insure the necessary high standard of physical qualifications; it was desired that the best physical material available be picked for this service. All the body mechanisms were carefully examined, such as the respiratory, cardiovascular, genito-urinary, muscular and visual, but in addition it was also deemed advisable in the case of prospective aviators to incorporate an examination of the vestibular apparatus, since such an examination throws light on the condition of the eighth nerve, medulla oblongata, pons, cerebellum and other portions of the nervous system, as well as of the ear itself as a motion-sensing organ. The degree of function of this mechanism could obviously be measured only by the responses obtained on stimulation. Nystagmus, being one of the important and the most easily measured of the responses, naturally received its share of attention in the examination of every candidate for aviation.

QUESTIONING OF THE RELIABILITY OF THE NYSTAGMUS RESPONSE

The reliability of the nystagmus response as a measure of function of the vestibular mechanism has recently come to be questioned, curiously enough not by otologists, but by certain learned and prominent psychologists. They promulgated the theory that persons subjected to considerable whirling or tumbling, such as acrobats and equilibrists, lost their nystagmus as a result of their training. When such a person was examined he would then probably show an impaired or absent nystagmus, which would therefore brand him as one having a subnormal vestibular apparatus, and hence unfit for aviation. This would mean a loss to the air service of the work of a very valuable man. Furthermore, they stated that fliers within the aviation service after having flown a considerable time would probably lose their nystagmus as a result of the whirling they were subjected to while in the air, and when reexamined would then be found below the required physical standards and taken off active flying.

This contention, that there is a suppression of the eye reaction in persons subjected to certain types of acrobatic exercises, would, of course, be a serious matter in the consideration of the examination of the vestibular apparatus from a general medical standpoint. If, for instance, patients on examination would exhibit a much shorter duration of nystagmus than the normal 24 seconds, it would naturally have no definite significance, since there was no telling how practiced the particular individual under consideration was in the matter of rotation. That is, he may have been fond of dancing or tumbling or what not.

This point of view may be summed up briefly, thus: A reflex reaction may disappear as a result of frequent repetition; this disappearance need not necessarily indicate a pathologic condition. Clinical medicine has for years relied on the permanency and constancy of reflex phenomena. Medical men have come to place a great reliance on the appearance or nonappearance of the knee jerk, the elbow jerk and the pupillary, Babinski and other reflexes. The assumption, therefore, that one may develop a tolerance and eventually fail to exhibit a reflex simply as a result of training is so contrary to the medical conception of the behavior of reflexes generally that it naturally became a subject of investigation at the Medical Research Laboratory at Mineola, L. I. The Otologic Department was particularly concerned in determining just how much reliability could be placed on the appearance or the nonappearance of nystagmus after stimulation, and just what effect continued practice would have on this interesting reflex.

RESULTS OF TESTS

Attention was first directed to the nystagmus reaction in fliers of varying experience. Flying generally, and stunt flying particularly, entails whirling to such a marked extent that any person who has flown thousands, or hundreds, of hours has certainly undergone more practice in whirling than most persons would undergo throughout the ordinary course of their lives. These examinations revealed uniformly that fliers of even 2,000 hours' flying experience continue to exhibit a good active nystagmus of the usual duration, approximately 24 seconds. Wherever possible these results were checked up with the nystagmus findings of the same persons at the time of their original examinations when they first entered the service, and in no instance was there found a reduction in the duration of nystagmus. We examined at Mineola 942 veteran fliers. The average duration of the nystagmus after turning to right was 24.8 and after rotation to left, 25.08 seconds.

Not content, however, with the results of the examination at Mineola, similar investigations were conducted by trained otologists at the various other flying fields throughout the country, with identical results. Capt. Louis Levy,[1] M. C., an otologist unusually experienced in the method of conducting this special examination, reports the results of his personal examination of a consecutive series of 541 aviators, in which the average duration of the nystagmus after turning to the right was 24.6 seconds and the average nystagmus after turning to the left, 24.4 seconds. Lieut. Charles R. Brenner, M. C., another trained observer, reports sixty-three consecutive examinations of fliers, whose average flying experience is 128.4 flying hours. The average nystagmus after turning to right is 25.3 and after turning to left, 25.4.

All the foregoing findings in fliers are sufficiently convincing to have it definitely settled once and for all that army aviators do not lose their nystagmus as a result of the rotation and whirling to which they are subjected. Therefore, when a flier, who on admission had a normal nystagmus, is found at some later time to have a marked impairment of this reaction, it is due to some other cause than flying per se.

---

[1] Levy, Louis: Vestibular Reactions in Five Hundred and Forty-One Aviators, J. A. M. A. **72**: 716 (March 8) 1919.

The usual statement that acrobats and whirling stage-dancers lose their nystagmus is not borne out by our investigations. We have examined numbers of such persons, and they uniformly show a normal nystagmus. Leut.-Col. E. R. Lewis, M. C., reports vestibular examinations of a number of such persons. The nystagmus observed is given in Table 1.

The average nystagmus in these whirling artists, turning to the right, is 26.1 seconds, and turning to the left, 26.05 seconds. These findings certainly suggest that the occupation of the subjects had no tendency whatsoever to diminish the duration of nystagmus. In fact, they exhibit normal reactions.

TURNING-CHAIR TESTS

There was also started at Mineola a series of experiments in which persons were subjected to frequent rotation in the turning-chair so that it could be determined just what effect, if any, such frequent and continuous rotation would have on their after-turning nystagmus. This experiment was suggested to the otologic department by the report of a similar series of experiments carried out by a group of observers trained in the observation and study of psychologic phenomena. These psychologists reported that persons who started with a nystagmus of 24 seconds or more on being subjected to daily turnings for several weeks would show either a complete loss of the nystagmus reaction to turning or a marked diminution. Since these experiments were conducted by observers not experienced in this type of examination, and as no medical examination had been made to determine whether or not the subjects of their experiments were normal, the results could naturally not be accepted by otologists without corroboration. The Otologic Department of the Medical Research Laboratory at Mineola, therefore, saw fit to conduct a similar series of experiments. Ten adult persons were carefully selected and examined. The caloric test was performed, that is, each ear was douched with cool water. They were also examined in the turning-chair, and in addition the galvanic reactions were taken. In this manner it was determined that they were absolutely normal. Six of these subjects were turned to the right and left daily. Four subjects were turned in the same manner twice daily. Two subjects had many additional turnings, as much as 440 rotations in one day. The results of the nystagmus reactions in these cases are given in Table 2.

Throughout these tests it will be observed that now and then a day was skipped. This could not be avoided, since all of these subjects were enlisted men who because of other duties occasionally could not appear for the examination. These lapses, however, were so rare—about one day in seven—that they certainly have no effect on the findings. These records clearly indicate that:

1. Not a single subject has lost the nystagmus.
2. Not a single subject has shown even a marked impairment of the nystagmus reaction.

Careful analysis of these findings discloses that there appeared a slight reduction in the duration of nystagmus after two or three weeks of turning in *some* of the cases. Even this apparent shortening of the duration of nystagmus, however, was rather an increased proficiency of those subjects in "gaze fixing" than actual lessening of the stimulus. The daily practice of fixing the gaze at a distant object, which was required of them after each test, taught them the art of holding the eye more or less fixed voluntarily, so that the nystagmic excursions became smaller. That this was produced by training, resulting in an increased fixation control of the voluntary eye movements, and not the result of a change in the character or intensity of the vestibular stimulus, is suggested by the fact that it occurred only in a few subjects—in those more apt. Furthermore, it was demonstrated that placing a pair of plus 20 degree planoconvex lenses in front of the eyes of those subjects immediately brought back the original duration of the nystagmus. Observation of the resulting nystagmus made *behind* those lenses as well as *through* them confirmed beyond question that there was no real reduction of the duration of nystagmus following these experiments. Further turning, for three or four weeks, in which the convex glasses always were used, revealed no reduction whatever in the duration of nystagmus.

As stated, all the subjects received a complete examination of the vestibular apparatus before these experiments were undertaken. This examination included turning, douching and electrical stimulation. On the completion of the experiments—after nine weeks of daily rotation, another complete examination was made, and the findings on douching and from electrical stimulation gave results identical with those obtained on the very first examination. This simply furnishes additional evidence that the eye response to vestibular stimulation was not altered in these persons.

This finding is particularly interesting in the consideration of the relation of eye responses in their bearing to medical diagnosis generally. The fact that such a prodigious amount of whirling stimulation did not affect in the slightest degree the responses, obtained by douching, seems to confirm the principles long recognized in otologic practice. It emphasizes once again what perhaps was not quite clear to some observers: that impaired nystagmus after ear stimulation must be considered as the direct result of pathologic impairment of some of the nerve pathways that conduct the impulses from the ears to the eyes.

CONCLUSIONS

1. The duration of after-turning nystagmus is not impaired by flying. Such a very large number of aviators have been reexamined as to make this conclusion absolute and final.

2. From the evidence at hand, it would seem that in acrobats, whirling dancers, airdrome performers, and in athletes in general, there is no diminution of the nystagmus response. More examinations of such persons, however, would be necessary before any final conclusion should be drawn.

3. Repeated turning experiments on normal persons occasionally produce an "apparent" and slight shortening of the nystagmus, but that this is only apparent and not real is demonstrated by the convex glasses.

4. In medical practice, an absence or impairment of eye responses following ear stimulation definitely indicates a pathologic condition within the vestibular mechanism.

STREPTOCOCCUS HEMOLYTICUS IN WAR WOUNDS *

First Lieutenant, M. C., U. S. Army

A. E. F., FRANCE

The data presented herewith have been obtained in a study of the bacteriology of war wounds as seen in Base Hospital No. 43. We realize that studies made in a hospital in which the period of time from the incurrence of the wounds until their study is shorter may give an entirely different picture. However, we think that some conclusions of value may be drawn from the work here presented that may add to our general knowledge of the subject. A few of these patients came directly from the first aid dressing stations, some being seen with the original dressings intact. Many came later, while a considerable number had been transferred from other base hospitals.

This study includes 704 consecutive cases, in which 1,848 cultures were made from 985 wounds. Cultures were made of all wounds except very slight superficial lacerations. There was no selection of cases. With reference to the location of wounds, 48 per cent. were of the lower extremities; 26 per cent. of the upper extremities; 18 per cent. of the head and neck, and 20 per cent. of the trunk. Of those of the lower extremities 18 per cent. were with fracture and 82 per cent. without fracture; of those of the upper extremities, 33 per cent. were with fracture and 67 per cent. without fracture; of those of the head and neck, 18 per cent. showed fracture, while 82 per cent. were without fracture, and of those of the trunk, 10 per cent. were with and 90 per cent. without fracture. When seen the first time by a medical officer, 40 per cent. were designated as "serious" and 60 per cent. as "slight" (these data being taken from the field card). The average length of time from the incurrence of the wound until a culture was made was ten days, the shortest period being one day and the longest thirty-seven days.

---

*From Base Hospital No. 43 (Emory Unit).

METHODS AND MEDIUMS

The first 130 cultures on ninety-seven wounds were made directly on blood agar plates. The method used was to place a small amount of the infected material on the plate and spread it over the surface by means of a bent platinum wire. Afterward incubation colonies resembling *Streptococcus hemolyticus* were transplanted to tubes of the same medium. In this series only 7 per cent. of positive cultures of this organism were found. Subsequently, after suggestions were received from the Central Medical Department Laboratory to the effect that Dunham's peptone, to which a small piece of fresh rabbit liver had been added, be used, the latter method was adopted and has been followed consistently. On account of the difficulty in securing rabbit liver we tried beef and human liver, which seemed to give the same results as the rabbit liver. The peptone was made up — 1, tubed in 5 c.c. quantities and then about 1 gm. of liver was added to each tube. This was then sterilized in the autoclave at 10 pounds for fifteen minutes. The liver turns dark, and there is a cloudy sediment which settles at the bottom of the tube, leaving the supernatant fluid clear. This medium was made up in large quantities and enough kept on hand at all times for a large number of cultures. On the arrival of a train bringing wounded, one officer and an enlisted man were placed at each surgical section with all material necessary to obtain smears and cultures from all wounds. In addition to taking the cultures, the clinical appearance of the wound was noted. When considered necessary, smears and hanging drops were made and examined in the operating room. In some very serious cases these investigations determined the course to be followed by the surgeon. But cultures were made for future confirmatory diagnosis. The cultures were made by means of sterile swabs introduced into the wounds and immediately inoculated into the liver peptone medium. These cultures were examined by the hanging drop and Gram's stain of smear at the end of six or eight hours. In some cases the streptococcus developed in from four to five hours in this medium. The hanging drop gives most valuable information at this stage. The cocci appear in long and short curved chains. We have not been able to demonstrate any motility of the chains of cocci. At the same time it may be determined what course to follow for the identification of other aerobes and anaerobes when original independent cultures were not made for anaerobes. A preliminary report from this study is submitted to the surgeon in charge of the case. All tubes showing growth are transplanted to blood agar plates. After incubation of the plates for from eighteen to twenty-four hours in the inverted position, isolated colonies with well defined colorless zones of hemolysis are picked and transplanted. For the further identification the methods adopted by the Medical Department of the Army were followed.[1]

GENERAL OBSERVATIONS

Of the total number of wounds, 24 per cent. were found to harbor *Streptococcus hemolyticus.* The clinical appearance of the wound gave no information as to the probable presence or absence of this organism. This was especially noted by Major Frank K. Boland, M. C., chief of the surgical service, and by other members of the surgical staff, as well as by members of the laboratory staff. Some of the wounds that appeared fairly clean would harbor this organism and would respond much more slowly to treatment than others apparently much more severely infected but which would clear up almost magically with the use of neutral solution of chlorinated soda (Dakin's solution). A further observation was that the bacterial count came down much more rapidly in those wounds in which *Streptococcus hemolyticus* was absent. Although these streptococcus wounds did not respond as rapidly as the others to Dakin's solution, no other method of treatment was found that was an improvement over this method. The early observation thus made with reference to the significance of the kind of bacteria contained in wounds led us to regard as of minor importance the bacterial count. In fact, the bacterial count, even when carried out with the most exact technic, can compare in no way with the bacterial cultivation of wounds. It is of some value in following the progress of the wound from day to day, but its use alone gives very little idea as to the kind of bacteria present. Thus a wound containing many harmless saprophytes may be closed successfully, whereas any wound showing a positive culture of *Streptococcus hemolyticus* should not be closed. Further, the number of smears suggesting the presence of this organism is much less than the number actually shown to be positive by culture.

In connection with this work, an investigation of the possible carriers of *Streptococcus hemolyticus* at this hospital was made. Of 308 medical officers and nursing personnel (nurses and orderlies), throat cultures showed 1.6 per cent. to be carriers. Of 600 patients, exclusive of those with respiratory disease, 5.2 per cent. were carriers.

MORTALITY

In the total series there were five deaths directly attributable to *Streptococcus hemolyticus* infection.

CASE 1.—A. B. had a multiple gunshot wound of the left arm. The severity of injury necessitated amputation at the evacuation hospital, 1 inch below the surgical neck of the humerus. *Streptococcus hemolyticus* was isolated from the stump on arrival here ten days after amputation. A blood culture was positive for this organism. Seven days later the patient developed a streptococcus meningitis, which proved fatal on the fourth day.

CASE 2.—J. K. had a multiple gunshot wound affecting (1) the face through both mandibular rami, (2) the left hand (penetrating), (3) the left foot (perforating), and (4) the right thigh (middle third, perforating). The patient recovered from initial shock. Wounds 1, 2 and 4 improved rapidly. Wound 3 showed, on culture, *Streptococcus hemolyticus.* Two weeks later a blood culture was positive for the same organism. The patient succumbed to septicemia sixty-nine days after primary injury.

[1] Methods for the Isolation and Identification of the Streptococcus Hemolyticus, Adopted by the Medical Department, U. S. Army, June 1, 1918.

routine use of cathartics in a hospital is a reflection on the dietitian.

8. There is, of course, a special group of diseases, such as nephritis, diabetes, cardiovascular diseases, gastro-intestinal disorders, acute surgical cases, etc., which by general consent must be treated by special dietary therapeusis. The problem of meeting the needs of these patients does not ordinarily confront the mess administration, as such diets usually are and should be prescribed by the surgeons in charge, the mess personnel acting in a capacity strictly analogous to that of the hospital pharmacist.

PREPARATION OF THE MENU

The mere enumeration of these classes indicates the necessity of a variety of menus. In few hospitals is there sufficient differentiation. Perhaps the most frequent source of dietetic blunders is an attempt to feed the hospital corps men and patients together. In such cases practically always one class or the other is improperly fed. Even patients who are essentially normal are engaged in highly sedentary occupations and should be treated accordingly. The "regular" meals usually are sent to a considerable number of borderline cases. Among these are men whose digestive capacity is not equal to unlimited demands. There should, therefore, be a definite forbidden list which includes corned beef and cabbage, sauerkraut, fried bologna, and other sophisticated meats, fried cabbage, pickled pigs' feet, and other such indigestibles. All of these have been encountered in the patients' "regular diet" at one hospital or another. They should have no place in an institution where they are likely to reach men who may be harmed by them.

In some hospitals, physical conditions make it difficult to segregate patients and corps men. If the same kitchen and dining room are used for the two groups, they should be fed at different times and with differential menus. These are compiled with certain dishes, such as roast beef and potatoes, to be served to both groups. To patients whose caloric requirements are low, "light" vegetables—creamed celery, for instance—and "light" desserts are served; for the corps men whose requirements are high, such "concentrates" as beans, rice and bread pudding, are added to the meat and potatoes. Any competent dietitian can apply this system at length.

Military patients generally want to eat to repletion. They may be allowed to do so if the menus are properly designed. But appetite cannot be relied on for adequate regulation of consumption. Many eat merely for amusement. Feeding a man 3,600 calories, however, when he needs only 1,800 calories, is to waste food inexcusably. The menus should be so planned that food of bulk to fill an ordinary stomach will furnish only the proper number of calories. Stewed and fresh fruits, and the coarse vegetables should be utilized freely. The statement that "the men will not eat turnips, etc.," merely means that the hospital cooks are incompetent. The coarse vegetables are eaten with relish when properly prepared. In some hospitals the training of cooks is only half done. They should all have a "postgraduate" course in "cookery for the sick" to be given by the dietitian, such as the "diet cooks" usually have had.

Bed patients and ambulant patients cannot properly be fed the same meals. In some hospitals all bed patients except those on forced feeding receive the "light" diets. If the menus are properly written, this is a good practice.

The subacute febrile patients and convalescents mentioned in Class 6 should have menus planned especially for attractiveness, utilizing the greatest feasible number of "concentrates," such as ice cream, lima bean purée, lactose custard, etc. A common plan is to give these patients the "regular" diet supplemented by feeding between meals. This is at best a makeshift device. The planning, preparing and serving of such meals should be under the supervision of skilled dietitians. The situation presents problems that will tax both the scientific knowledge and culinary skill of the best of these.

Much useless expenditure of mental energy occurs in hospitals where new menus are worked out every day. A standardized set can be devised and used repeatedly. The individual menus, however, should not be repeated oftener than once in ten days. A regular weekly sequence of meals soon becomes very distasteful to those patients who are in the hospital for relatively long periods. When the interval is ten days, however, few detect the repetition. To insure wide utility, the basic items should be printed in heavy type, with substitutes indicated in smaller type, as in the accompanying dinner menu.

DINNER

TOMATO SOUP
Okra soup
Vegetable soup
ROAST BEEF
Mutton
POTATOES
Sweet potatoes
BREAD
Corn bread

SPINACH
Kale
Cauliflower
Cole slaw
RAISIN PIE
Bread pudding
Rice pudding
COFFEE
Tea

BUTTER
Gravy

The provision for substitutes makes the system elastic so that the menus can be adapted to seasonal and special conditions. Since the work does not have to be frequently repeated, it is practicable and desirable to indicate on the menus the amount of protein and the caloric value of standard servings of each item. To determine approximately the caloric and protein consumption of any patient or any ward becomes then a matter of simple arithmetic.

The practice in vogue in some hospitals of leaving the menu writing to the mess sergeants is scarcely defensible. These men are practically always incompetent to meet the special technical problems involved. The same may be said of men who have had only ordinary medical training. It is unfortunate but true that dietetics in the ordinary medical curriculum receives but scant consideration. Neither does experience in managing hotels fit one to prescribe diets for hospital patients. Hotel diets are better adapted to putting men in hospitals than to getting them out. Special knowledge of the theory of nutrition, the art of cooking, and of dietary therapeusis are needed. The best method of meeting the problem is to place the supervision of nutritional affairs in the hands of a surgeon well versed in the theory and practice of dietetics. But in most hospitals no such man is available. The next best plan is to place a good dietitian in charge both of compiling the menus and of supervising the preparation of food for all the patients.

METHODS OF SERVING AND THE ELIMINATION OF WASTE

There remain to be considered the problems of serving and the closely related problems of waste control. Food waste in the military hospitals has been observed to vary widely—from 0.4 ounce to approximately 2 pounds per man per day. The problem of controlling waste amounts to one of preparing the food properly and compelling all soldiers to refrain individually from wasting: low wastage follows from good cookery and good discipline. As an added factor, a certain amount of instruction in the best technic of serving is advisable.

Much unprofitable discussion has been devoted to the question of whether cafeteria line service or table service is better. By either system waste can be kept down to an insignificant amount, and very high waste has been seen under each. In this respect there is very little actual choice between the systems; but as a matter of maintaining a pleasant atmosphere in the dining room, skilfully administered table service is distinctly the better.

A common source of waste is the kitchen itself. Carelessness on the part of the cooks may result in spilling or burning foods. In hospitals where this occurs more than rarely the assessment of the wastage against the pay of the culprit, or in case he is not known, against the pay of the sergeant in charge, has a salutary effect approaching 100 per cent. in efficiency.

Careless peeling of vegetables, and especially of potatoes in the final stage after they have been through the peeling machine, is often encountered. The eyes have to be removed by hand; instead of using the point of the knife and removing a small bit, the common custom is to cut off a tangential slice thick enough to include all the eye. For such vegetables as carrots, and in hospitals that do not have a peeling machine for potatoes, curved (semicylindric) knives should be provided. Allowing bone to leave the kitchen before going through the stock pot is another source of waste, although one not frequently encountered. Using fat trimmings or rendered fat to stimulate a slow fire is an extravagant method in use by some cooks. This should be strictly forbidden. The fat should be used in the cooking to as great an extent as possible; any not thus used should be sold, preferably for food elsewhere. The use of good food fat for soap, as has been practiced in some institutions, is a "conservation" measure of dubious value. A skilful use of "leftovers" is essential to satisfactory kitchen economy. If the quantity in any given case is too small to serve as part of a dish for the whole mess, "side dishes" should be made for a few only. The leftovers, to insure palatability, should be "worked up" at once rather than allowed to accumulate.

Assuming that good food has been provided and properly cooked, the methods of serving play the predominant rôle in encouraging or discouraging waste. In case the cafeteria line service is used, alert, intelligent men should be placed in charge of the dispensing. They should not be allowed to forget that their efficiency is an important factor in the success of the service. Each man in the line, as he presents his plate, should be given an option as to whether or not he shall receive any particular viand. In all cases relatively small initial helpings should be served and dependence placed on rehelpings ("seconds") to insure that the men get as much food as they need. Bread should be cut in half slices, a half inch thick, and the men given an option as to how many of these shall be taken. In view of the wide variability of bread consumption by different individuals, it would be better in all cases to put the bread at least on the tables and allow the men to help themselves. Some mess officers do not favor the plan of serving half slices, on the ground that even with whole slices the bread wastage is low. They overlook the fact that when whole slices are served, many men will eat more bread than they want in order to get the small quantity they do desire. The waste is just as great when a man overeats as when he empties food into the garbage can.

The next necessity is the "clean plate" rule: "Take all you want, eat all you take." This does not apply to the inedible portion, but the so-called inedible portion is subject to some control. Fat should not be considered inedible. The man who does not care for fat should not have it put on his plate. Proper carving and proper serving meet this difficulty. In enforcing the "clean plate" rule, two factors are important. Better results are obtained when both cheerful cooperation of the men and good discipline are brought to bear. When a man understands that the amount of food in the world is very inadequate and that what he wastes some one else who needs it has to go without, he is generally willing to be careful. When human beings are starving to death by the thousands, food waste becomes a crime. This fact should be emphasized rather than the money saving idea. The soldier is not particularly impressed by appeals to save money for the government and thus keep down taxes. Good discipline, however, is also necessary for the ignorant, the vicious or the careless. The simplest and most effective method is to place a good sergeant in charge of the dining room and require him to see that all edible food is eaten.

By these methods edible waste can be kept below a half ounce per capita daily.

When table service is used, the same general methods apply. The essentials are good food, well cooked and properly served to well disciplined men. With table service the "food hog" may offer a special problem. He is the man who takes the most and the best of the dessert or of the meat without regard to the rights of his neighbors. This difficulty is usually seen in hospitals where discipline is slack. It is generally best to deal with each man directly and not let the habit spread. If the mess, however, has got out of hand, squad service should be established; that is, the men come to the dining room in small groups in charge of squad leaders, preferably noncommissioned officers, who are held personally responsible for proper service and for wastage.

A combination of table and line service in some situations is the most satisfactory, the meat and dessert being served to the men directly, and beverages, soup, bread and vegetables placed on the tables.

Cream and sugar for beverages should also be placed on the tables. No man can properly sweeten another man's coffee. The consumption of sugar is usually higher when the men help themselves, but not greatly so. At Camp Jackson it was found in line organizations to require 0.063 pound more per man per day when the sugar was placed on the tables. This adds about one-half cent to the daily ration cost. Attempts to save sugar in the mess generally result merely in the men's buying more candy at the canteen. Another phase of the problem is that sugar may be left undissolved in the bottom of the cups. Good discipline meets this difficulty easily. If the men get careless, penalize them by sugarless days. An occasional sporadic case may best be dealt with individually. For sanitary reasons it is best to use some sort of container from which sugar is poured instead of dipped. These can be obtained from the hotel supply trade, or can be improvised from baking powder cans by cutting a hole a half-inch in diameter in one side near the top of the can.

As to "cream," if, as is usually the case, condensed milk is served, there is no legitimate objection to its being used in beverages as freely as desired. Many patients do not get enough milk for their own good. Milk is the best source of calcium and certain vitamins. At least 4 ounces of condensed milk or 8 ounces of fresh milk should be used per man daily.

The most important source of waste in some hospitals is one that is hardly even suspected, that is, waste due to overconsumption of "concentrates." A large stomach full of roast pork, mashed potato, gravy, lima beans and raisin pie is for a hospital patient a very wasteful meal. The man who needs only 2,000 to 2,500 calories may and frequently does eat 4,000. This excess is truly waste and is also detrimental to the patient himself. Many mess officers are unduly impressed by the wishes of the men for a heavy meat diet. In addition to retarding convalescence, this is expensive. The food is a part of the treatment. The aim should be to cure and discharge the patient, not to render him unduly happy and contented.

WARD SERVICE

The foregoing principles can be applied in theory and largely in practice to ward service. The food should reach the wards in an attractive condition and should then be served to the patients without deterioration. Hot viands should be served *hot*, and cold *cold*. This does away at the start with an important cause of wastage. When to a patient whose appetite is capricious at best an unattractive, lukewarm conglomerate of lumpy mashed potato, stewed tomato and hash is served, there will be a great deal of garbage.

A high degree of individualized service is feasible. When physical and sanitary conditons permit, the food carts should be taken into the wards and each patient served individually. When this is not feasible, the food can be passed in the containers and the patients served directly. For that class of patients who need forced feeding but whose appetite is capricious, this system should not be used. Such patients should have meals prepared and served with special attention to attractiveness. To them the sight and smell of large quantities of food are often highly distasteful and may seriously interfere with nutrition, and hence prolong convalescence.

The first helpings should be small, such as the least rather than the most hungry man will want. These can be supplemented by rehelpings to any desired extent. In every case, bread in half slices, cream, sugar, salt and pepper should be passed separately. Generally there is nothing except ignorance or indolence to prevent a service so well adapted to individual patients that ward waste drops to a low figure. If the serving is properly done, the "clean plate" rule can be enforced to nearly as great an extent in the wards as in the dining rooms.

Ward serving needs especial supervision. Many nurses and attendants, if left to themselves, adopt the easiest way. An officer or dietitian should be placed in charge. Frequent inspections of the serving in each ward should be made. Any serious defects encountered should ordinarily be taken up with the ward surgeon who is primarily responsible for ward conditions.

All leftovers should be kept clean, and except in the case of contagious wards, should be returned to the kitchen. Allowing ward attendants or convalescent patients to stuff themselves with attractive leftovers is a fairly common practice, but one in which the involved waste is merely concealed.

The ward personnel should not be allowed to make surreptitious use of delicacies ordered ostensibly for the patients. Unless care is taken to prevent it, there may be a considerable waste of such materials as fruit juices, milk, cream and eggs. The rule should be adopted—and enforced—that no food or beverages except water be consumed in the wards by any one other than the patients at any time. Frequent check should be made on the amount of special commodities sent to the wards, and the issue of special meals or delicacies should be restricted to legitimate demands. A *laissez faire* policy along this line inevitably leads to abuses.

In supplying food to the contagious wards, special effort should be made to send only such quantities as are likely to be needed, since leftovers from these wards should not be returned to the kitchen.

In the larger hospitals in which there is frequent changing of the population in the wards, special methods are needed to keep the mess officer apprised of the dietary needs of each. The standard plan of requisitioning once daily is inadequate. At least supplementary reports of transfers and discharges from the wards are needed. In some hospitals, confusion would be lessened by systematically requisitioning about an hour before each meal. In one hospital studied, all meals sent to the wards in excess of the actual number of patients were charged to the surgeon at 25 cents each. The method seemed to be as effective as it was unpopular.

In some of the best hospitals, intramural publicity has been used effectively to keep down waste. The amount from each ward and each kitchen is weighed separately and recorded. Reduced to a per capita basis, it is then reported. The surgeon in charge of each ward, or the sergeant in charge of each kitchen, the waste of which is higher than the average, should be notified of that fact and urged to reduce it below the average. Each man thus in improving his own record aids in lowering the general average. This procedure, carried out for a few weeks, has been found materially to lower the garbage output.

SUCCESS UNDER DIFFICULTIES

Perhaps in no part of the military establishment has the attempt to spring to arms over night resulted in more trying conditions than in the hospital kitchens. Very few cooks, almost no mess officers with adequate technical training, and at first no dietitians were available. When the need became recognized, a considerable number of hotel managers patriotically offered their services, and they have done an invaluable work. A few well trained hospital mess sergeants were also available for promotion to commissions and also have been very valuable. More recently dietitians have come to play a large part in hospital messing. They have introduced technical skill in adapting dietaries to the nutritive requirements of the hospital population and have added an element of finish to the diets which have very materially improved conditions. Their lack of a definite military status has made large demands at times on their tact, and their success is so much the more to be admired.

EMPLOYMENT OF CALIPERS IN FRACTURES OF THE FEMUR

DENNIS W. CRILE, M.D.
Captain, R. A. M. C., Harvard Unit
EDMONTON, ENGLAND

In view of the extensive use to which the caliper has come, as introduced into general practice by Lieutenant-Colonel Besley, U. S. Army, I think it may be useful to put forward some observations in regard to the many points that have arisen. These observations are based on the study of about 300 cases, which I have been able to follow closely during the past year, and the casual observation of many others.

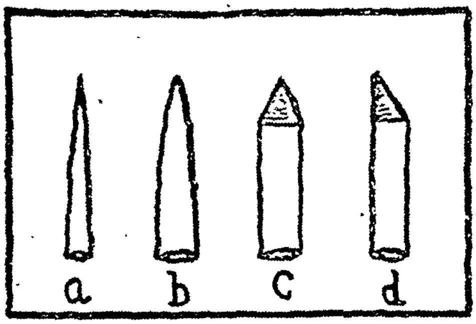

Fig. 1.—Various shapes of caliper points: *a*, long, thin and tapering; *b*, long, thick and tapering; *c*, short taper, concentric point; *d*, short taper, eccentric point.

It is my belief that in this instrument we have realized one of the benefits that go to justify the sacrifices made by so many splendid heroes. However, it can be misused, misapplied and abused. The outstanding virtue of the instrument lies in the fact that a direct force can be applied to the bone without damaging it and without penetrating its cortex. Penetration of the cortex means misuse of the instrument or some fault in construction.

The dictum of Thomas in regard to his splint applies equally to the caliper: "Do not try to modify the Thomas splint until you understand the use of the Thomas splint." Thus, as with so many Thomas modifications, we find the modified caliper inferior, as a rule, to the original.

PENETRATION

The question of penetration of the cortex depends on many factors. Chief among them is the actual shape of the caliper points. The point that is sharp and of a long, thin taper is the worst type. It presents a spearhead to the bone and is so constructed as to penetrate the maximum depth with a minimum pressure (Fig. 1). The relative length of the handle arm compared to the gripping arm is important. The longer the handle arm, the greater is the leverage in favor of penetration; and, on the other hand, the shorter the handle arm, the greater the likelihood of slipping due to insufficient grip.

In addition to the length of the handle arms, their pitch bears on the question of leverage; thus, a caliper whose handle arms diverge markedly gives greater leverage in favor of penetration than one in which the handle arms lie closer together (Fig. 2).

The arrangement of the cords at the handle ends has much to do with the grip pressure and therefore is important in considering the cause of penetration. The diagrams given in Figure 3 illustrate this and are the results of careful experiments. The force applied was in each case constant—8 kilograms—and acted in the long axis of the calipers. It was counterbalanced, but the lateral (grip) pressure was balanced by spring balances acting right and left from a fixed point to the respective arm. It will be seen that the grip pressure varied considerably and that the less the grip pressure the greater the spread of the points. From the series of experiments showing the variation in grip pressure with different spreads of the points (Fig. 4) it will be seen that with a constant type of cord fastening, the greater the spread the greater the grip pressure. Thus it follows that the influence on grip pressure of the type of cord fastening is even greater than appears in Figure 3. The pull as taken in Figure 3 *e* exerts sufficient grip pressure to prevent slipping, provided the handle arms are prevented from moving outward by a tie between the handle arms. Figure 5 shows the influence of an eccentric pull on grip pressure and also the rotation and sluing tendency produced by an eccentric pull. Figure 5 *d* shows that with eccentric traction the greater pull is exerted on the same side from which it is taken, not on the same solid crossed arm.

The position on the femur in which calipers are applied is important also regarding penetration. If the caliper is applied on the flat tuberosities of the condyles, where the cortex is thin and comparatively soft, the tendency is to facilitate penetration, while the higher on the shaft one goes, the harder, thicker and more like ivory the cortex becomes. On the sloping surface just above the condyles the surface of the bone is rough and not glazed, but very hard and thicker than directly over the condyles. Here is the place where a grip can be most easily obtained with the least inward pressure, for two reasons: The surface presented is almost at right angles to the direction of the caliper points, and it is rough and hard. It has the disadvantage of not being so near the skin as the tuberosities of the condyles; but to counteract this it has the advantage of not being directly beneath the ligamentous bands passing from the thigh to the leg, namely, the iliotibial band and the tendons of the long adductors and sartorius. Major Pearson has shown that these structures, when the knee is moved, tend to drag on the caliper points and may thus cause erosion and penetration.

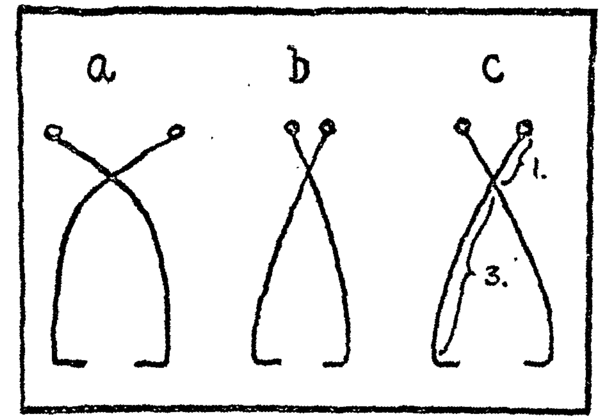

Fig. 2.—Length and pitch of handle arms: *a*, long, with obtuse angle; *b*, short, with very acute angle; *c*, good proportions, with acute angle and a leverage of 1:3.

In my experience it has never been necessary to bore small holes in the bone to receive the caliper points. This, it seems, tends to render penetration of the cortex more easy, since the most resistant part of the bone is the very outermost layer of the cortex. Boring this, then, gives the caliper point an excellent start and for this reason should not be done. Captain Preston advocates tapping the caliper points gently a little way into the cortex. However, by pushing with the hands the points will find sufficient grip to hold any necessary pull without slipping, provided other factors are eliminated.

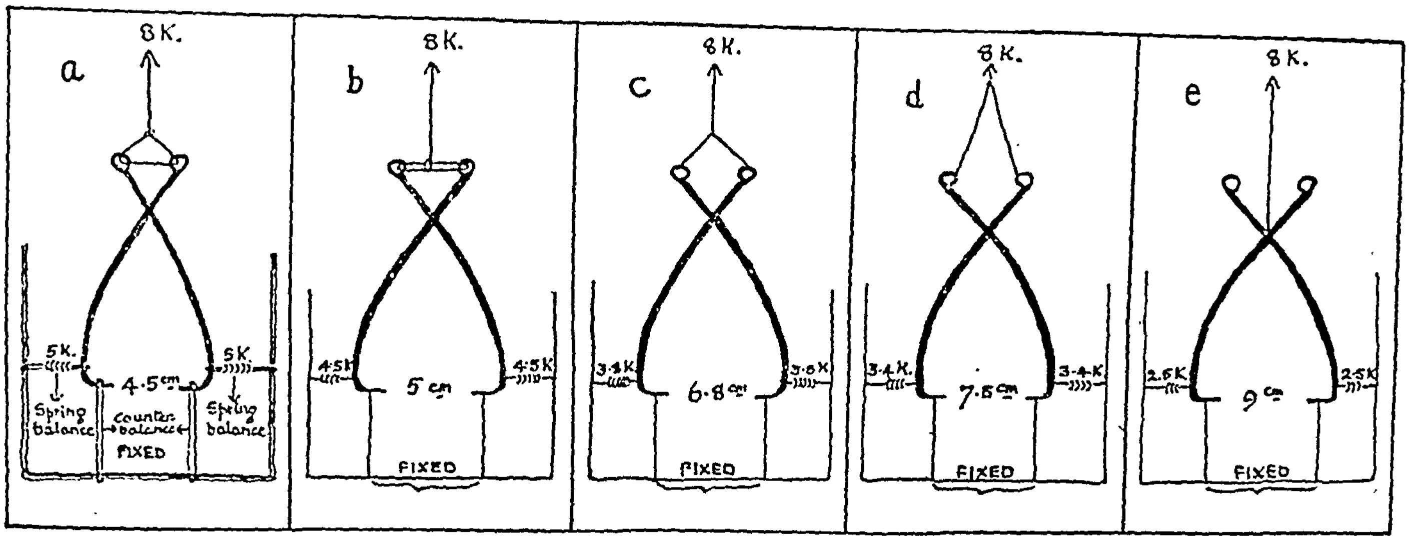

Fig. 3.—Changes in grip pressure due to various arrangements of cords at the handle ends.

JOGGLING

To my mind the most important factor causing penetration is joggling. By this is meant the constant vibration which must be transmitted over the pulleys from the weights and which is instigated by the body tone and movement to and fro. Gross movement is not referred to but a constant, fine, vibratory joggle; and its action is comparable to that of a convict trying to bore a hole through a brick wall with a nail. If he simply presses the nail against a brick, little or no result will follow; but if he joggles the nail or twirls it, he soon penetrates the brick. In the bones no rarefication occurs about a sterile screw or nail driven in and stationary; but if there is movement against it, it rarefies a space about itself. One finds that 90 per cent. of the calipers that cause discomfort have eroded a space about their points; and thinking back from this, it follows that joggling is at the root of the evil, generally combined with some other error. The caliper that does not erode or slip causes no discomfort and feels like an integral part of the man who wears it. If weight and pulley extension can be made to produce 1 cm. of lengthening (over the normal leg) inside of a week, and then a tie-on fixed extension is substituted, with the ring of Thomas slung so that it hangs an inch above the mattress, the calipers are comfortable always.

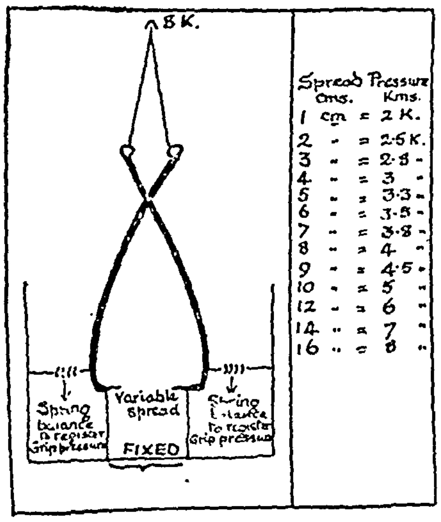

Fig. 4.—Variation in grip pressure with different spreads of the points.

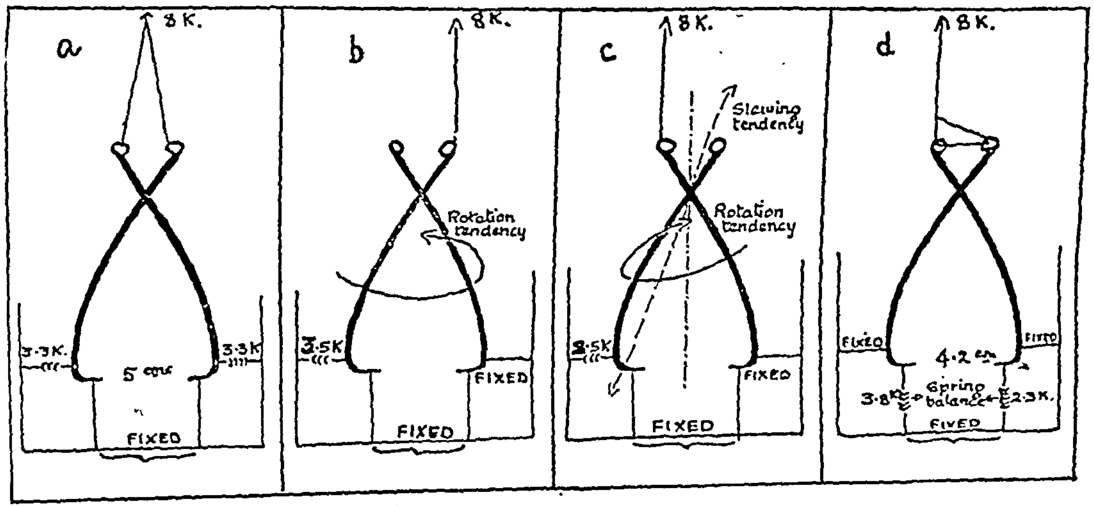

Fig. 5.—Influence of an eccentric pull on grip pressure and also the rotation and sluing tendency produced by an eccentric pull.

One should remember, as Sir Robert Jones has pointed out, that as long as the muscles must be on guard against movement in the fracture, they will not relax. This applies to all weight and pulley extension since there is a constant possibility of sudden jars with each bodily movement. When the patient is put on fixed extension, this possibility is removed and the muscles relax and one can see them do so. This being the case, the pull on the caliper points becomes negligible, and thus a factor in favor of penetration is removed. I do not advocate a tie-on extension until the limb is overlength which, with calipers in an early case, should not be more than a week and may be facilitated by the simple means of a ratchet on the weight and pulley made by having a knot in the cord about 6 inches proximal to the end of the Thomas splint. From this knot a cord is carried over the end of the splint and back to the knot twice, where it is tied (Fig. 7). Each day, as the weight and pulley gain a little length at the fracture, this ratchet cord is retied, thus holding by fixed extension any gain that may have been obtained by weight and pulley (Fig. 7). It detracts nothing from the efficiency of the weight and pulley, and it is very valuable in practice.

In order further to reduce the possibility of joggling, it is advisable at the time of application to tie the handle ends of the caliper together with a cord which passes through each eyelet twice, since it can then be drawn tighter. This then prevents any outward movement of the gripping points, so that they cannot loosen their grip if the weights are bumped against, lifted or jolted, either grossly or minutely. The grip of a caliper depends for its evenness and efficiency on a perfectly steady pull. Any variation of the pull, no matter how slight, means a variation of the grip pressure, and this is joggling and means erosion and pain, or penetration, or both.

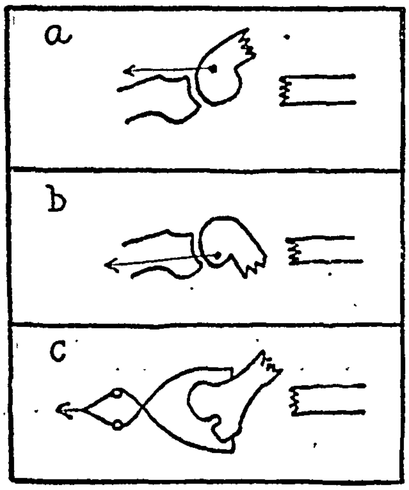

Fig. 6.—Results of applying calipers at different points; *a*, overelevation of lower fragment; *b*, depression of lower fragment; *c*, adduction of lower fragment.

CHECK APPLIANCES

To my mind the important points to be borne in mind in the prevention of penetration are: (1) a short, broad, tapering point; (2) the prevention of minute joggling; (3) application to the hard part of the bone; (4) low leverage (short handle ends not diverging too much), and (5) check appliances. There are several appliances in use at present to check penetration by putting a stop between the handle ends of the calipers. The theory is, that if a block is put there, the gripping points are prevented from coming closer to each other. This is true; but this in itself does not prevent one point from penetrating while the opposite point is pushed away from the bone and thus slips. I have seen this happen frequently when long, sharp, tapering points were used (Fig. 8).

The check caliper as designed by Major Pearson is an improvement on the old method of putting a block of wood between the handle ends. He employs a screw which can be set only to check approximation of the points at any width. I find that a screw locking both approximation and spreading is more satisfactory (Fig. 10.) The points which tend least to penetrate and yet always grip firmly are such that they present progressively a blunter end the nearer together they come (Fig. 1 *d*). The point tapers quickly from the full diameter of the gripping arm to a sharp point. The entire taper is on the side away from the direction of the pull. This leaves a broad surface to present to the bone and permits only of a tiny grip, but one which will not slip and which, owing to its breadth, resists dragging.

The question of the corroding of points and consequent slipping does not apply to short, heavy points, for it will take months for a heavy point to corrode off, since it must be a peripheral corroding equal all around. The narrow, long point corrodes at a place about one-sixteenth inch from the actual point, which then suddenly breaks off and the caliper slips. This objection can be met by making the points of rustless steel, which, however, does not prevent a long, sharp point from penetrating. The ordinary Besley caliper with points corrected by filing and with the handle ends tied together with cord (the pull being taken from a separate cord and not from the cross cord) will perform its function quite satisfactorily. There is, however, the objection to them all that the knee cannot be fully extended without the caliper arch impinging on the tibial crest, which then becomes a fulcrum, levering the caliper points upward and thus causing dragging on soft parts and periosteum (Fig. 9 *a*).

Thus, when the splint is removed and union is firm, the knee cannot be fully extended, and often for a long time after the patient walks, he must take the weight in the slightly flexed position, which means a weak leg and a limp. It also delays the use of an ambulatory while the knee is being straightened. Further, all the time the patient has been lying in bed, his quadriceps has been on the stretch disproportionately to the rest of his muscles, and a certain amount of tone is thereby lost which sometimes is never regained. Then, too, the pad of fat beneath the ligamentum patellae and the deposit of fat in the ligamentum mucosum increase in size markedly toward the end of convalescence and, since the knee has been in the flexed position, offer resistance to straightening.

I do not think that these things outweigh the tremendous advantages which the caliper gives us in length, position, early union, early clearing up of sepsis, decreased number of cases of acute medullary osteomyelitis, stiffness and stiff ankles, and pressure paralyses of the external popliteal nerve. Nevertheless, this is a disadvantage. This drawback has been met by designing a caliper which permits the pull to be taken from the sides so that the caliper can be in an upright position, and from buttons on the side cords lead along the leg to the distal end of the splint. Thus the caliper arch will never impinge on the tibial crest, and the knee can be fully extended (Fig. 9 *b*).

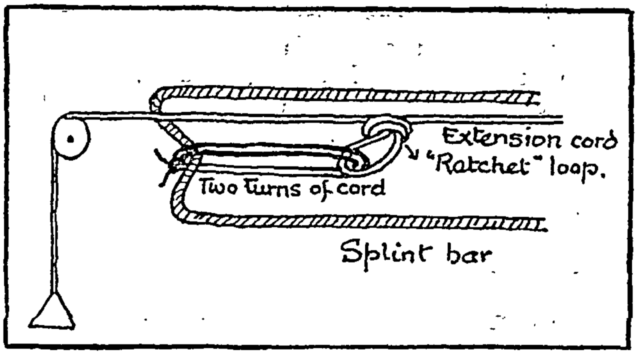

Fig. 7.—Ratchet arrangement.

This caliper has many advantages over the old Besley model, but has the objection of expense. The distance between the points is controlled in both directions by a screw which passes through the body of the caliper and locks it (Fig. 10). It is fixed rigidly to the bone so that no joggling can occur, there is no tendency to progressive penetration, and its points are broad and short. I find it perfectly comfortable and efficient, permitting full motion in the knee. It can be applied to the tuberosities of the condyles, since it will not penetrate even this thin cortex, and thus has the advantage of being subcutaneous and more safely applied.

By safely I mean that the synovial landmarks are more definite, while with the higher application, the subcrural pouch, especially on the external side, stands in danger of being penetrated. For special supracondylar fractures the same caliper equipped with double points, such as I have used since March, 1918, and a side arm as suggested by Captain Kilner, for controlling elevation or depression, can be used with advantage.

The causes of pain in caliper points in my experience are: (1) motion of the calipers in relation to the bone, and (2) edema and consequent pressure surrounding the points, being either periosteal or subcutaneous. The first occasions 90 per cent. of the discomfort I have seen. The second, which may depend on the first, being due to the presence of an irritating, joggling foreign body, calling out a leukocytosis which is sterile, occasions the most severe pain and is the cause of most of the caliper failures. I have never seen pain after the first forty-eight hours from a caliper which could not move or joggle in relation to the bone. One often finds penetration of the cortex associated with pain, both probably attributable to motion.

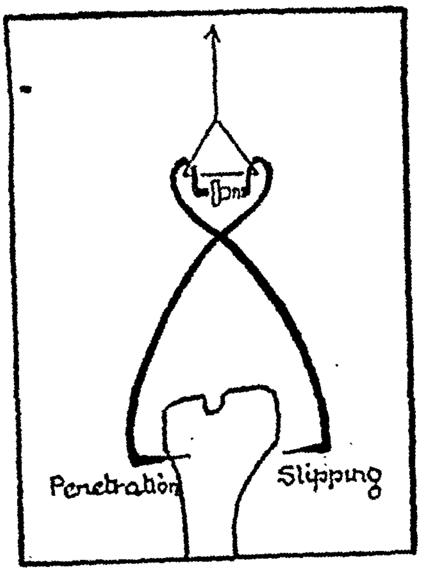

Fig. 8.—Check appliance between handles that does not prevent penetration and slipping.

A SATISFACTORY METHOD OF APPLYING CALIPERS

According to a method of applying calipers that I have found very satisfactory, the skin is cleaned for twenty-four hours beforehand with alcohol. It is unnecessary to move the patient from his bed. I prefer chloroform or ether anesthesia, although nitrous oxid and oxygen can be used satisfactorily. The patient is always given ¼ grain of morphin and 1/100 grain of atropin beforehand. While the patient is being anesthetized, the pulleys, cord, weights and knee flexion piece are made ready by an assistant. It is desirable to have the condyles well above the level of the splint bars rather than sagging down in the slings, as then they are more accessible.

When the patient is anesthetized, the skin over the condyles is painted with iodin. Sterile towels are placed about the knee. An incision 1 inch long is made longitudinally just proximal to the adductor tubercle and carried only down to, and not through, the deep fascia. This is packed with gauze to control all oozing, and then directly at right angles to the line of the tibia the opposite incision is made in the same way, on the outer side of the knee. When perfectly dry, both incisions are rubbed thoroughly with bismuth iodoform petrolatum paste and the caliper points pushed through the fascia and deep tissue to the bone. It is wise to scratch the periosteum from a small area with each point before making them firm. This does away with all pressure on the periosteum, which is very sensitive, and prevents the collection of serum beneath it, thus obviating the most usual cause of aching at the caliper points. To make the caliper firm I press hard with the heel of each hand against the gripping arms until I feel them bite into the cortex. An assistant then passes a cord through the eyelets twice and ties very tightly so that the caliper is prevented from releasing its grip. A dry gauze dressing is then applied; being carefully packed into the incisions so that no serum shall remain to become a source of leukocytosis. The points should be inserted through the most proximal ends of both incisions, so that when the pull is put on they will not touch the skin edge, which is sensitive.

The skin incision is made larger than is necessary to admit the points so that if any serum accumulates later or if the tissue becomes edematous, no pressure can develop, and therefore no pain results. The incision is not carried beyond the deep fascia because then no other instrument, save the actual calipers, can carry slight infection to the depths of the wound. Further, there being no necessity to bore into the bone, no avoidable damage is done. Certainly, the fewer instruments used, the less risk is run, and since the calipers themselves suffice, I see no reason for complicating the operation.

The bismuth iodoform petrolatum paste is merely a fetish and gives one the feeling that no infection can pass through its antiseptic barrier. It seems to leave the points of application drier and less edematous than other antiseptics seem to do.

The screw-locking caliper described above is applied in the same way except that it is screwed home instead of being pushed, and is applied to the flat surfaces of the condyles, not proximally to them.

As regards the point of application of calipers, the fracture itself is an important factor in deciding the exact point of application. For instance, in supracondylar fractures, the point of application is of the utmost importance. If one applies calipers in a position relatively anterior on the tuberosities of the condyles, the application of force in a direction parallel to the femur tends to overelevate the lower fragment (Fig. 6 *a*). If one applies them in a posterior position, the reverse is the case and they tend farther to depress the lower fragment (Fig. 6 *b*). If one applies the inner

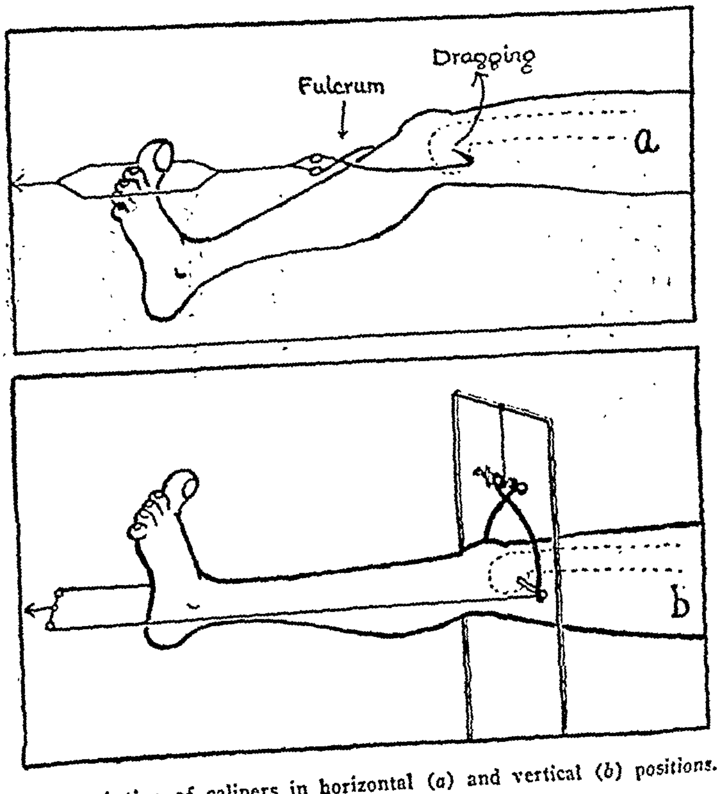

Fig. 9.—Action of calipers in horizontal (*a*) and vertical (*b*) positions.

point more proximally than the outer point, the lower fragment will be adducted and the calpiers will pull mostly on the more proximal point, which will then tend to penetrate and slip (Fig. 6 *c*). If one applies the outer point more proximally, the reverse is the case. Both points, when one desires a straight pull, must be applied on either end of a line drawn at right angles to the line of the tibia. This line represents the axis of the femur, although its shaft inclines from this line. This inclination is compensated for by the offset head. If the inner point is applied in an anterior position and the outer in a posterior position, there seems to be only a slight tendency to produce rotation inward. This screw-power for rotation can be increased by using a double cord instead of the single one. letting each cord wrap around the splint bars.

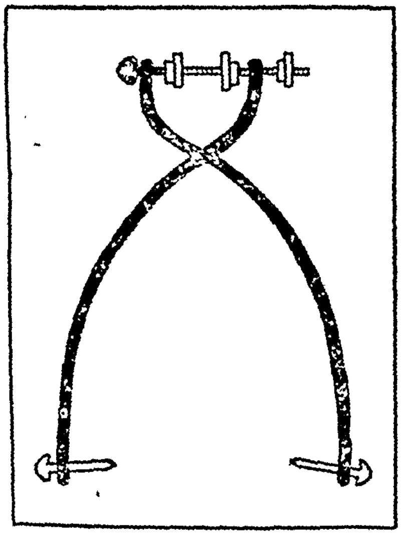

Fig. 10.—A screw that locks the caliper.

Any of these facts may be turned to advantage in correcting malalinement, or may be abused in ignorance. Figure 11 shows the available surface for caliper application. It is always safe to apply the points on the most prominent points of the condyles. These are never covered by synovia. However, before attempting to apply calipers to any other spots, one should study the synovia, the course of the anastomotica magna artery, the external popliteal nerve, and the functions of the various ligaments around the part, as well as the cortex of the bone.

The direction of the pull is important, and much may depend on it. The rule is to pull in the long axis of the bone. Departure from the rule may be advisable only in exceptional cases and after due consideration. If one has properly applied calipers the rule need never be departed from.

The amount of pull will vary according to the shortening to be overcome, the strength of the musculature, the age and site of the fracture, the amount of swelling, the tenseness of the deep fascia, and the degree of infection. It is my custom to apply 15 pounds directly.

If this promises, after twenty-four hours, to stretch the fractures sufficiently, it is enough. If it seems not to perform its function, which can be from ¼ to 2 inches per day, it is increased to 20 pounds, which is sufficient to stretch almost any fracture full length, provided the apparatus is correct. One need not hesitate to use 25 pounds, or even 30 pounds for a few days, and often forcible reduction under an anesthetic may be resorted to. If the extra weight causes periosteal pain, it can be reduced. One finds that 10 pounds is the least that avails fully, although others can get results with only 5 pounds, I am told. However, one aims to get a little overlength inside a week and thereafter to hold this gain by tie-on fixed extension, which in reality takes very little pull once overlength is accomplished.

The calipers will probably cause discomfort and even pain for the first forty-eight hours. During this time morphin should be given freely, since then the patient lies still and gives the points a chance to settle down. The weights, too, can do more efficient work. If morphin is withheld during this early stage, the patient is restless, and every movement only further irritates his fresh wound. Later on, after three or four weeks, one may find the points again causing pain. This will usually be a throbbing and is due to a sterile leukocytosis and edema about the points. A course of fomentation over the whole front of the knee region, especially applied at night, will soon ease this and dispel the edema. This pain is usually due to some slight erosion and should not occur with well applied and correct calipers. However, one's early cases will show these things, and occasionally a patient whose calipers are perfectly applied will complain. Relief can be given sometimes by running the needle of a hypodermic syringe along the caliper point and squirting a small amount of 2 per cent. cocain around the point. A tiny pinch of powdered procain applied as a dressing to the caliper points is often very efficient. Whenever any serum appears about the points, they should be washed and dressed with eusol or some mild lotion. Sometimes temporary reduction of the weight may give permanent relief, so that it may be all reappled comfortably. Under no circumstances should all the weight be removed or lifted, as then the caliper grip lets go and the caliper will surely slip. This applies only to the old nonlocking model. Sometimes the weight can be divided, and part applied through an adhesive extension to the leg, while the caliper pull is reduced. If all attempts to relieve pain fail, the calipers may be reapplied through fresh incisions at a little distance from the old ones and preferably above them. No case of sepsis has been seen in more than 300 cases which amounted to more than slight local inflammation. The knee joint has not been involved. Twice the anastomotica magna artery has been ruptured with the development of small aneurysms necessitating ligation of that artery.

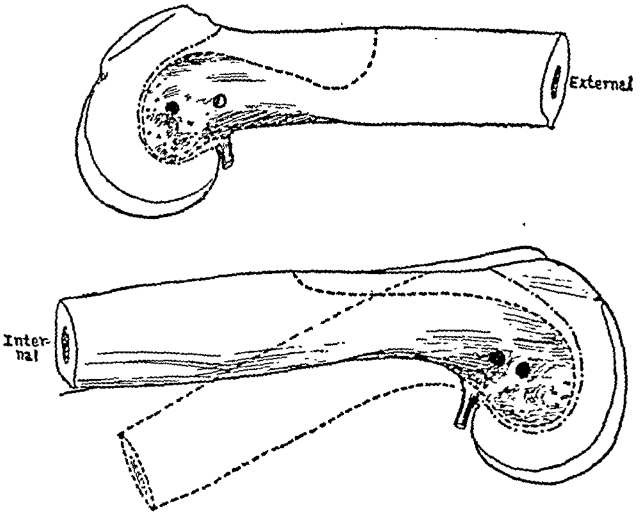

Fig. 11.—Available surface for application of calipers.

The caliper is, of course, applicable to other bones than the femur. My experience is largely confined to its use on the femur alone, although on several occasions, in the treatment of fractures of the femur, I have used it on the lower ends of the tibia and fibula, the tibial tubercle and os calcis with good result.

As regards sinuses resulting from the use of calipers, it seems that they occur only when the medulla has been penetrated; and when calipers of proper construction and intelligent application have been used, the tiny incision seals in a few hours after the calipers have been removed, and in a week it is healed and stays healed. The scar is not painful and does not interfere with motion of the ligaments about the knee joint. However, I do not advocate the use of calipers by men who have not studied the principles underlying their action.

Captain Preston, working at Taplow Military Hospital, has had splendid success in the treatment of fractured tibiae and fibulae, and Capt. W. Grant Waugh has used the caliper with success on the humerus.

Clinical Notes, Suggestions, and New Instruments

REPORT OF A CASE OF RETROGRADE URETERAL CALCULUS

Ester M. E. Sundelöf, M.D., Fall River, Mass.
Roentgenologist, Truesdale Hospital and Clinic

In January, 1918, a patient in whom there was a retrograde movement of a ureteral calculus was referred to me. Though Kretschmer[1] has since reported two cases of the sort, I was unable at that time to find a report of a similar case.

REPORT OF CASE

History.—A man, aged 29, first appealed for medical advice in March, 1917, when he had his first attack of pain in the right back radiating into the abdomen, right thigh and penis. This was associated with vomiting, voiding of bloody urine and frequent desire to void. The attack required a number of hypodermic injections of morphin for relief. Three months later he had four similar attacks within ten days. He had always been delicate as a child, and had all the diseases of childhood. The father and mother were living and well. There was no tuberculosis or cancer in the family. The patient's habits were good.

Physical Examination.—He was a small, poorly developed man. His color was good. The skin was active. The pulses were normal. The pupils were equal and reacted to light and accommodation. The external ocular movements were normal. The tongue, teeth and throat were normal. The heart was of normal size and of good muscle tone; there were no murmurs. The lungs were clear, front and back. The abdomen was negative, but during an attack there was marked rigidity of the abdominal wall. The extremities were normal.

Urinalysis, after attacks, had always shown the presence of red blood corpuscles.

Roentgenoscopy, June 18, 1917, by Dr. John H. Lindsey, gave no evidence of stones in either kidney. There was a calculus at the lower end of the ureter below the brim of the pelvis on the right side.

Roentgenoscopy, Jan. 18, 1918, gave no evidence of stones in either kidney. There was a calculus at the lower end of the ureter below the brim of the pelvis on the right side.

Operation, Jan. 19, 1918.

Cystoscopy revealed the left ureter and the bladder normal. The catheter could not enter the right ureter.

Operation.—January 19, by a suprapubic incision, the peritoneum was opened, but no stone was found at the site indicated by roentgen ray. The ureter was dilated to the size of a man's thumb, and 3 inches from the bladder wall there was a moderate constriction. A probe was passed into the bladder without meeting any obstruction, and no grating feeling was detected. Exploration of the upper part of the bladder was negative. The ureter was tied off near the bladder, and the wound closed and drained with one rubber dam through a stab wound. As it was felt that this procedure had not benefited the patient, and since the right kidney felt hydronephrotic, a right nephrectomy was done. The stone was found in the removed kidney. The patient died two hours later of surgical shock.

Postmortem Examination.—The stone had evidently rested on a stricture of the ureter, and when the patient was tipped into a slight Trendelenburg position to free the pelvis of intestine, the stone had fallen back into the kidney and dropped into the lower calix, where it was out of reach of the probe.

SUMMARY

A patient gave typical symptoms and signs of a stone in the ureter. Two roentgen examinations, seven months apart, showed the location of the stone in the ureter in exactly the same position below the brim of the pelvis. There were no stones in the kidneys. Subsequent operation failed to reveal the stone on the position designated by roentgen ray. The right kidney was removed because it was hydronephrotic, and the stone was found in the kidney that had been removed.

At the time I was asked why I had not stated in my roentgenographic report that the stone was or might be movable; but I had never heard of a similar case, and could find no reports of similar cases in the literature available. I am offering this report to add to the few cases that Dr. Kretschmer and others have already sent in.

EPIDEMIC OR LETHARGIC ENCEPHALITIS (NONA)

The name "encephalitis lethargica" was coined by Economo,[1] who described a group of cases of this disease occurring in epidemic form in Vienna in 1917. It describes a condition primarily characterized clinically by lethargy and pathologically by polioencephalitis. This term has been cricitized by English observers since it applies a clinical adjective to a pathologic substantive; the term "epidemic encephalitis" has seemed to some English authorities preferable. In this connection, Economo referred to a mysterious condition called "nona" which occurred in Italy and Hungary in the spring of 1890. Netter[2] has pointed out that, although this disease is new to present observers, on two occasions previously it has manifested itself in epidemic form, following the influenza epiedmic of 1890 in northern Italy and in Hungary, and appearing in the United States and practically all of Europe in 1895.

The first cases noted in England occurred in February, 1918, and the British journals during the first half of the year contained numerous suggestive case reports. A report recently issued by the Local Government Board of Great Britain with the assistance of the Medical Research Committee[3] recognizes the disease as an infection due to a specific virus.

PATHOLOGY

Professor Marinesco of Bucharest has said that the changes in the brain belong histologically to the class of polienccphalitic diseases which are inflammatory in nature. Clinically the available evidence, according to Wilson,[4] points clearly in the direction of an encephalitis amounting usually to an encephalitis of toxi-infective origin. The brains examined showed little macroscopically on the cranial surfaces beyond meningeal congestion, and, perhaps, a quite minor amount of patchy localized meningitis. On section, both gray and white matter were found to be the site of minute hemorrhagic areas scattered irregularly ("piqueté hémorragique" in Netter's phrase). Numerous necropsy reports failed to reveal any specific region of the brain as invariably affected, although there is no doubt that the regio subthalamica and the mesencephalon generally are as often affected as any other part. Motor cranial nerve nuclei are involved, while sensory nuclei escape. Microscopically, there is thickening of the leptomeninges with exudation or vascular congestion, and the gray matter is the site of perivascular cellular infiltration. In addition to these interstitial changes there are parenchymatous alterations in the shape of nerve cell degeneration and actual neuronophagia, as in poliomyelitis. Economo found evidence of regenerative processes in some of his cases.

BACTERIOLOGY

No recognizable organism has been detected in the tissues on microscopic examination. In a single one of Economo's cases an emulsion of the brain and cord was injected subdurally into a monkey by von Wiessner. The animal died in forty-six hours with symptoms of stupor for twenty-four hours previously. The brain was typical of hemorrhagic encephalitis, and von Wiessner recovered a gram-positive diplostreptococcus which he cultivated and which on injection into other apes produced somnolence and mental weakness. Von Wiessner states that a similar organism was found in all the human cases that he studied, but other observers do not mention such a finding.

CEREBROSPINAL FLUID

In all the reported cases the cerebrospinal fluid has been bacteriologically negative; the cell count has been increased in some cases.

CLINICAL SYMPTOMS

The most frequent characteristics are lethargy or stupor and symptoms indicating lesions in or about the nuclei of the third pair of cranial nerves. Usually there is fever in the early stages, the common range being between 101 and 102; but high temperatures have been reached in other cases. The pyrexia usually lasts from two to five days, but may continue longer. A period of subnormal temperature not infrequently follows. In the majority of cases a prodromal period may be recognized, but is not well defined. Usually the first symptom is simple catarrhal conjunctivitis, and in a smaller number of cases, tonsillitis, simple sore throat and bronchial catarrh; but the salient symptom observed in 80 per cent. of the cases was progressive lethargy. The onset is usually gradual, although in some cases the disease has been ushered in by a fainting attack. The patient becomes dazed or stupid, sleeps a great deal, and is drowsy by day. In marked cases, this lethargy is accompanied by heaviness of the eyelids, pain in the eyes, blurred vision, photophobia, headache, dizziness, and in some cases, diplopia and gradual passing into stupor. In some instances mental hebetude is associated with a highly emotional state, but in others the mental depression is so great that melancholia may be suspected. To summarize: The most frequent and characteristic signs in the prodromal period are lethargy, asthenia, vertigo, headache, diplopia and some alteration in the mental state.

After the prodromal period the symptoms of infection become manifest with febrile reaction, the patient lying in bed, often unable to make any voluntary muscular movement, the face expressionless and mask-like, and there may be double facial paralysis. Nocturnal delirium is not uncommon, and there may be rigidity. In a considerable portion of cases the voice becomes nasal and monotonous; sentences are uttered slowly, the words slurred into one another. But in some cases, once started, the patient chatters sentences with so great a rapidity as to be unintelligible. The commonest sign is ophthalmoplegia, which was recognized in 75 per cent. of the cases examined.

Dr. A. S. MacNalty, who contributes to the British report, recognizes seven types of cases: (*a*) clinical affection of the third pair of nerves; (*b*) affections of the brain stem and bulb; (*c*) affections of the long tracts; (*d*) the ataxic type; (*e*) affections of the cerebral cortex; (*f*) cases with evidences of spinal cord involvement, and (*g*) the polyneuritic type in which affection of the peripheral nerves is suspected.

PROGNOSIS

The prognosis is usually better than is suggested by the alarming state of the patient. In the British report it is stated that of 168 cases, thirty-seven deaths were recorded. Economo reports six fatal cases out of eleven; Netter, seven of fifteen; von Wiessner, two of thirteen, and Findlay,[5] one of three. The duration of the stupor is variable, lasting from two to three days, and more often from two to five weeks, and in one case in which the patient eventually recovered, for eight weeks. Certain manifestations have persisted in some instances after the expiration of three months from the day of onset. These were an alteration in the mental condition, persistent cranial nerve palsy, the appearance of paralysis—apparently of spinal cord origin—and athetosis. In one of Findlay's patients, after five months, there remained a right sided facial paralysis, ptosis of the right upper eyelid, left external squint, and a general mental apathy.

TREATMENT

No specific method seems to be available, most authorities agreeing that the best that can be done is to put the patient to bed, providing him with good nursing, and perhaps with transient relief through withdrawal of cerebrospinal fluid. Warmth applied to the limbs is a remedy for pain, numbness and tingling. It is recommended that no opiates be given.

NOTIFICATION

This condition has been made notifiable in England. Since it is not clear to what extent the condition is a specific infection, it would appear to be desirable that the disease be made notifiable in general so that epidemiologic studies may be made in addition to bacteriologic studies on the etiology of the disease.

EPIDEMIC OR LETHARGIC ENCEPHALITIS

Acute Infectious Ophthalmoplegia, Acute Encephalitis, Nona?

This unfamiliar disease, many cases of which were observed in England and France early in 1918 and in Vienna in the winter of 1916-1917, when von Economo suggested the name "encephalitis lethargica," now seems to be making its appearance in various parts of this country. In the recent discussion on influenza before the Institute of Medicine of Chicago, Bassoe[1] stated that during the last few weeks he had seen several cases which were characterized by marked drowsiness and paralysis of cranial nerves, especially the ocular, and which otherwise corresponded to the clinical picture of lethargic encephalitis, and that he knew of similar observations by other physicians. Last week Pothier[2] reported the clinical details of eight cases from Camp Lee, Va., and Neal[3] mentions the occurrence of cases in New York.

In previous editorial discussions[4] of the European, especially the English, reports on lethargic encephalitis, special emphasis was placed on its similarity to the cerebral and bulbar forms of epidemic poliomyelitis, and it was suggested that further investigations might show "the new disease" to be true epidemic poliomyelitis. In the meantime, the report[5] of an extensive collective investigation of lethargic encephalitis (168 cases) has appeared from which we learn that, while nothing by way of a causal agent has been demonstrated, intracerebral inoculations of monkeys with emulsions of diseased nervous tissue failed completely to produce any results. As the monkey is readily susceptible to such treatment with similar material from cases of epidemic poliomyelitis, the present indications are that the two diseases are separate and distinct, and this conclusion is borne out also by certain clinical and epidemiologic differences to which attention has been called, by Netter in Paris, especially. It is noteworthy, however, that the anatomic changes in the two diseases are of the same general nature, and MacNalty[6] ventures the suggestion that the relation between epidemic poliomyelitis and lethargic encephalitis may be comparable to that between typhoid and paratyphoid fevers. The English investigators consequently regard lethargic encephalitis as due to an as yet unknown virus which causes inflammatory changes, especially perivascular infiltrations, in the basal ganglions, the upper part of the pons, especially in the gray matter of the floor of the fourth ventricle, and in less degree elsewhere in the medulla. It is distinctly a polienceplialitic disease: the outstanding clinical features are a more or less pronounced lethargy, often progressive, and paralysis of the third and less often other cranial nerves.[6] Ophthalmoplegia was observed in about 75 per cent. of the English cases.

It is noteworthy that cases appear to occur with the general symptoms of fever, lethargy and weakness, but without paralysis, and hence are easily mistaken for more common infections, though perhaps of the greatest importance in the spread of the disease, which now is notifiable in England and Wales. At present, however, no new cases seem to be occurring in these countries. The results of further and more complete observations of lethargic encephalitis as it occurs in this country will be awaited with special interest.

It is quite remarkable that while English and other European observers do not seem to place any special stress on the relation of the newly recognized disease to influenza, the American cases so far reported are associated by the observers, particularly Bassoe[1] and Neal,[3] more or less directly with influenza. Four of Pothier's[2] eight patients are said to have had influenza a few weeks before they came down with lethargic encephalitis. While the question thus raised cannot be answered at this time, the information we now have indicates that it is only in connection with epidemics of influenza that anything definitely resembling lethargic encephalitis is described in the older literature.

It is said that profound and prolonged sleep has been observed in connection with many epidemics of influenza since early times. Zuelzer[7] mentions that in the epidemic of 1712, somnolent conditions were so frequent and so marked that in Tübingen, for instance, the disease was known as sleeping sickness, and Longuet[8] gives a quotation from Camerarius which appears actually to describe ophthalmoplegia. Coming down to more recent times, we find that in the early nineties of the last century, at the time of the influenza outbreak of 1889-1891, quite a little was written about a since forgotten disease called "nona" (also "la nonna"), which is said to have occurred especially in northern Italy and Hungary, but also elsewhere, and of which lethargy and weakness were pronounced manifestations.[9] At about the same time cases of ophthalmoplegia with stupor and somnolence were described by Blanc, Mauthner and others,[10] and the question was raised then whether "nona" was not a kind of ophthalmoplegia. "Nona," however, failed to establish itself as a definite disease, and was soon forgotten completely.[11]

TAKING CHANCES IN BLOOD TRANSFUSION

Transfusion of blood or blood constituents has become a necessity in modern clinical practice. Its general utility is unfortunately still limited by a number of difficulties of technic and incompatibilities of blood that have not been satisfactorily mastered. None of our present methods—the syringe cannula, the paraffined tube and the citrated blood procedures—are absolutely free from all objectionable features, among which unanticipated hemolysis, agglutination of the corpuscles, and febrile reactions are included. Of the dangers due to incompatibility we shall consider particularly those due to agglutination rather than those due to lysis.

In 1900, Landsteiner first suggested that human beings might be divided into definite groups according to whether or not the corpuscles of one were agglutinated by the serum of the other, or vice versa. His preliminary grouping into three classes was subsequently shown to be somewhat inaccurate, and numerous examinations made since that time have definitely shown that there are four groups. As long ago as 1907, Hektoen[12] said: "From the practical point of view, isoagglutination of human corpuscles is of immediate interest in connection with the determination of the opsonic index and with transfusion of blood." It will be remembered that in 1906 Crile had successfully transfused blood from normal to diseased human beings. Hektoen also said, in commenting on this achievement: "The occurrence of isoagglutinins in human blood suggests that under special conditions homologous transfusion might prove dangerous by leading to erythrocytic agglutination within the vessels of the subject transfused." Since 1906, transfusion has been performed on such a multitude of persons in such a great variety of disease conditions that there is good evidence to show the necessity for again repeating the warning of Hektoen to the effect that the presence of these isoagglutinins in human blood may be a danger during transfusion. Cases of transfusion in human beings with seemingly unfavorable results due to cross-agglutination were reported by Schultz (1910), Hopkins (1910) and Ottenberg (1911).

The subject has been somewhat complicated by the introduction of the citrate method of transfusion, whereby the agglutination of the blood during transfusion is prevented by the addition of a small quantity of sodium citrate. This method of transfusion, being relatively easy, has become quite a vogue, and has led many observers to believe that preliminary tests of the compatibility of donors' and recipients' blood are unnecessary. This appears to have been the case especially with some of those who utilized the transfusion of convalescents' blood as a means of treatment during the recent epidemic of respiratory diseases. Recently Pemberton has reported on 1,036 blood transfusions, and he further emphasizes the need of preliminary tests.[13] This large series of transfusions was made in the Mayo Clinic between 1915 and 1918, thirty-five of them by direct methods and 1,001 by the citrate method. Pemberton is convinced of the importance of preliminary tests before transfusion. He points out that Bernheim in 1915 collected data of 800 transfusions by twelve different operators, and reported hemolysis in fifteen cases with four deaths. In twelve cases in the series of transfusions in the Mayo Clinic there were group reactions. In every case in which the blood had been grouped by the microscopic test, the observers were able to locate later the error in the test, most of them due to clerical errors in recording the group of the donor or the recipient. He describes a typical reaction, such as occurs when transfusion is done between persons of incompatible groups:

> They occur early after the introduction of 50 or 100 c.c. of blood; the patient first complaining of tingling pains shooting over the body, a fulness in the head and an oppressive feeling about the precordium, and, later, an excruciating pain localized in the lumbar region. Slowly but perceptibly the face becomes suffused, a dark red to a cyanotic hue; respirations become somewhat labored, and the pulse rate, at first slow, sometimes suddenly drops as many as 20 to 30 beats a minute. The patient may lose consciousness for a few minutes. In one half of our cases an urticarial eruption, generalized over the body, or limited to the face, appeared along with these symptoms. Later the pulse may become very rapid and thready; the skin becomes cold and clammy, and the patient's condition is indeed grave. In from fifteen minutes to an hour, a chill occurs, followed by high fever, a temperature of 103 to 105 degrees, in which the patient may become delirious. Jaundice may appear later. The macroscopic appearance of hemoglobinuria is almost constant. In three such instances the symptoms were not recognized at the time of transfusion, and 500 c.c. of blood were injected. All the patients died,

[9] For reference to the literature on nona, which is well abstracted by Longuet, see Index Catalogue, Library of Surgeon-General's Office, Series 2, **7**: 945, 1902 (Anomalous and Unusual Forms of Influenza).

[10] Cited by Longuet (Footnote 8).

[11] The derivation and meaning of the word "nona" are obscure. It may have been a corruption of coma. Nona means literally ninth hour, and there is no evident connection between this meaning and the disease in question. "La nonna," a name also given the disease sometimes, means grandmother literally, and here again the connection is not evident. Nona is defined as follows in Foster's Encyclopediac Medical Dictionary (1894): "An alleged new form of disease reported in 1890 from northern Italy, Bavaria and Russia. It appears, however, that there is no foundation for the supposition that there is any such new disease, and that the reports are founded on cases of comatose typhoid fever, somnolence following influenza, and smallpox of an irregular and severe development."

[12] Hektoen, Ludvig: Isoagglutination of Human Corpuscles, J. A. M. A. **48**: 1739 (May 25) 1907.

[13] Pemberton, J. de J.: Blood Transfusion, Surg., Gynec. & Obst. **28**: 262 (March) 1919.

> two in one and three hours, respectively, following the transfusion, and one became comatose shortly afterward and died thirty hours later. In the other nine instances the symptoms were early recognized and interpreted, and the transfusion was concluded after the injection of 50 to 100 c.c. of blood. Adrenalin [epinephrin] and atropin were administered with good effect. There was no mortality in this group.

He concludes that these cases "point out most strikingly the fact that the injection of incompatible blood, namely, in which the donor's cells are agglutinable by the serum of the patient, is attended by the development of symptoms of the gravest nature, and that if these are not early recognized and the transfusion concluded before the injection of a large quantity of blood, fatal results are to be expected."

In the case of citrate transfusions, certain special untoward factors concerned have been made the subject of study in man by Drinker and Brittingham[14] at the Harvard Medical School laboratories. They have failed to observe any constant relation between the method of citration or the purity of the citrate used and the number of reactions. The objectionable component resides in the cells of the blood; for citrated plasma, thoroughly freed from all formed elements by prolonged high speed centrifugalization or by porcelain filtration, is singularly nontoxic, contrasting markedly with serum in this regard. On the other hand, the washed whole cell content of blood is uniformly toxic, whether injected into the individual from which the cells have been removed (plasmapheresis) or into different individuals who have been tested and show no agglutination or hemolysis of red cells.

A further analysis of the location of the factors in the cells responsible for the difficulties indicates that reactions decrease as the platelets are removed from the transfusion mixture. The Harvard investigators report that salt solution, red cells, white cells in greatly reduced numbers, and absence of platelets make the most perfect blood for transfusion that they have observed. Apparently changes in the platelets as a part of the process of coagulation represent a transformation responsible for the appearance of toxicity. The leukocytes themselves seem to be devoid of incompatibilities. Finally, they seem to have shown that citration harms the red cells, thereby promoting the possibility of hemolysis in otherwise compatible bloods. They found 44 per cent. of reactions with citrated blood, as compared with 20 per cent. of reactions when uncitrated blood transfusions were performed. They state that 20 per cent. is a decidedly lower percentage of reactions than has been obtained with any other method.

Contrasted with their small series, however, is that of Pemberton, who found only 219, or 21 per cent., of reactions in the 1,036 cases which he analyzes. Lewisohn[15] has also recently reported 200 cases, and is convinced that the frequency of chills is about the same with the citrate as with other methods. He, too, found reactions in 20 per cent. of his cases.

Thus, one by one, the detrimental factors in transfusion are being recognized. The next steps consist in devising ways to avert or eliminate them and thereby make a frequently desirable performance more dependable and less threatening.

WAR CHEMISTRY AND MEDICINE

The signing of the armistice and the prospect of a long, if not permanent, peace have lifted the veil of secrecy that has long hidden many undertakings of great scientific interest in connection with the war: Only a few months ago every one was saving fruit kernels and nut shells at the behest of the American Red Cross. It was vaguely known that the materials were to be converted into charcoal, which was to be employed in the manufacture of gas masks. But why these particular products were selected, what became of them, and how they act were questions that belonged to the great mass of mysteries developed by the secrecy of war time.

Colonel Burrell,[16] chief of the research division of the chemical warfare service, has at length disclosed some of the "inside history" of his service. The absorbent value of charcoal of a suitable sort is extraordinary. During its preparation, a film of hydrocarbons is likely to remain adherent to the surface of the particles. To remove this is highly important, because it seriously diminishes the absorptive power. American initiative, guided by chemical science, found a way to overcome the difficulty. By oxidizing processes the charcoal was cleansed of its hydrocarbon film and rendered active.

The extraordinary and utterly unexpected diversity of gases and other noxious substances employed by our enemies in their warfare[17] early taxed the ingenuity of all the Allies to devise satisfactory respirators. At first an alkaline solution was sufficient to protect against inhalation of chlorin; but when phosgen, prussic acid, xylyl bromid, chlorpicrin, bromacetone, and a succession of other equally formidable products had to be taken into account, cheesecloth impregnated with alkali or even with sodium phenate and hexamethylenamin no longer saved the wearer of the mask from untoward effects. The soda-lime finally developed and used in masks contained lime, cement, infusorial earth, sodium hydroxid, sodium permanganate, and water. Each ingredient performed a definite function. The lime furnished the main part of the absorption for acid gases, which it neutralizes, generally with the formation of calcium chlorid. The cement is used to make the granules sufficiently hard and yet not decrease the porosity, which is fatal to good absorption. Several other binders give equally good hardness, but all destroy the porosity. The infusorial earth is used to increase the porosity of the granule and thus permit the gas to have access to the interior and utilize the full absorptive capacity of the granule. The sodium hydroxid activates the rate of absorption of most gases, and, in addition, makes the control of the drying process more simple and tends to maintain the proper water content in the finished granule. The sodium permanganate is used primarily to oxidize certain oxidizable gases, which are difficult to absorb in gas masks. The water is necessary in making up a satisfactory mixture, and, after drying, a fairly definite moisture content is needed to get the best results in the absorption of gases.

[17] War Gases and Chemical Warfare, editorial, J. A. M. A. **71**: 1742 (Nov. 23) 1918.

Nor is the story of prophylactic measures against chemical modes of warfare completed with the description of the gas masks. Since most of the casualties from the widely used mustard gas were due to skin burns, it became necessary to devise suitable protective clothing. Gummed suits might be appropriate in winter, but they became a physiologic impossibility in hot days. Yet even this handicap was finally overcome by the designing of suits that were not impermeable to air and moisture, yet absorbed mustard gas vapor.

Some day an orderly account of the almost infinite variety of chemical problems that the government was called on to answer in this war will be written. It will be a story of fascinating interest. We shall learn how one scientist devoted his energies to the production of metal Dewar flasks for providing liquid oxygen to aviators; how another one spent days in finding the best way to disperse toxic solids or liquids, producing a fine powder or mist to penetrate masks; how many others worked unceasingly to synthesize new types of toxic compounds of arsenic or selenium or tellurium, whereupon colleagues tested their pharmacologic potency; how face masks with nondimming eyepieces were made comfortable for working and sleeping hours; how helium was extracted from natural gas to replace hydrogen in balloons. Now that the war is over we can pause to consider innumerable scientific advantages of the ceaseless labor and investigation of the past months. The thought that went into the war work, says a reviewer of its details, cannot be destroyed. The industries have gained much through the personal sacrifices of American chemists; likewise has medicine. The charcoal, the gas mask, the many potent new compounds, the liquid oxygen, the protective clothing, the dispersoids—these and dozens of other discoveries will surely find an application, somehow, somewhere, some day.

FOOD AND METABOLISM

It is becoming a common experience in these days to speak of food in terms of calories rather than ounces, and to make comparisons between different nutrient substances on the basis of their so-called energy or fuel values. The ordinary student of nutrition, as well as the casual reader of dietetic literature, is more than likely to gain the impression that, calory for calory, most foods are interchangeable so far as their nutritive value is concerned. The inadequacy of such a conclusion has repeatedly been emphasized in these columns. The food calorimeter gives no indication of the factor of digestibility, for example, without which concentrated calories are quite as worthless for human physiologic purposes as is a piece of anthracite coal. There is, furthermore, a growing realization of the inadequacy of the hypothesis of the "isodynamic replacement" or equivalence of foods which was so generally taught a few years ago. The ingestion of various foodstuffs is followed by an increased heat production, which Rubner designated as their "specific dynamic action" and which has proved to be somewhat of an obstacle to the acceptance of any simple theory of equivalence of food calories in nutrition.

For a long time the easiest explanation of the increase in metabolism after food ingestion was that it represents actual physiologic work and expenditure of energy incidental to the increased activity of the intestinal tract in the presence of dietary substances. Rubner has always denied this view, which was championed by the physiologist Zuntz. In an interesting symposium on the subject before the Fifteenth International Congress on Hygiene and Demography,[1] held at Washington in 1912, there was a general agreement that the different foodstuffs actually stimulate the metabolism, and, indeed, in unlike degree. The search for an explanation of this augmentation of metabolism, apart from any external work done, has been continued in the intervening years.

As this stimulation is particularly pronounced after the ingestion of nitrogenous foods in contrast with carbohydrates and fats, attention has largely been centered on the possible effects of absorbed amino-acids on metabolism. Some of the German investigators[2] have contended that "specific dynamic action" is an expression of the changes associated with the denitrification of amino-acids (derived from proteins by digestion) and the process of consequent urea formation. Recent studies of Lusk[3] at the physiologic laboratory of Cornell University, New York City, contradict this view. There is a very marked difference in the capacity of the various familiar amino-acids to increase heat production, quite aside from their behavior as antecedents of urea. In fact, the more probable explanation at present points to the non-nitrogenous rests of the amino-acids—to such compounds as hydroxy acids or keto-acids—as the effective agencies in the increased metabolism following the ingestion of protein. Either similar intermediary products in the breakdown of fats and sugars, or the metabolism due to a great plethora of the latter when they are ingested in abundance, may also occasion increased heat production when nonprotein foods are ingested in a large amount.

---

[2] Grafe, E.: Deutsch. Arch. f. klin. Med. **118**: 1, 1915-1916.

[3] Atkinson, H. V., and Lusk, Graham: Animal Calorimetry, XV, Further Experiments Relative to the Cause of the Specific Dynamic Action of Protein, J. Biol. Chem. **36**: 415, 1918.

The mathematical relation between the increase in heat production due to the ingestion of food and the fuel value of the intake is not inconsiderable in some conditions. Benedict and Carpenter,[4] who have termed it the "cost of digestion," estimate this to be not far from 6 per cent. on the average, in the case of carbohydrates; with fat the increase is about 2 per cent. of the fuel value of the intake, with a protein-rich diet approximately 12 per cent., and with mixed diets 6 per cent. Their experiments in the Carnegie Institution Nutrition Laboratory at Boston indicate that the mere work of mastication, such as would be involved in chewing gum continuously, may determine an increment in the heat production of approximately 17 per cent. Coffee, owing probably to its content of caffein, acts as a stimulant to metabolism. By eating a large meal of mixed foods it is easily possible to stimulate metabolism to 40 per cent. above the resting, basal value for a number of hours, and to 20 per cent. for at least eight hours. In this sense, then, we may truly speak of the stimulating effect of our nutrients in general.

Current Comment

THE VICTORY OVER RABIES

Amid the victories on the European battlefields that have thrilled the hearts of all warm-blooded Americans and every lover of democracy throughout the world, we may well pause for a moment to contemplate another type of victory—man's conquest of rabies, the dire disease that once meant a painful end for most of those who were inoculated with its deadly germs. Year after year the reports of the lives saved by the fruits of Pasteur's pioneer labors in combating the microbial enemies of mankind bring the story of the beneficent influence of this great Frenchman's contribution to medical science. While the names of great generals and distinguished statesmen are attracting foremost attention in the eyes of all the world, and men are rehearsing the conquests and combats of former great struggles, let us not forget the perennial victory over rabies. During the year 1916, according to a report recently issued, 1,008 persons from the district of Lyons received the antirabic treatment at the bacteriologic institute in that city.[1] A single death in this list places the mortality at 0.099 per cent. Since 1900, more than 9,000 persons have received antirabic inoculations, with a total of nine deaths, or 0.09 per cent. The story has become an old one; but it will long bear repetition as an eloquent testimony to the blessings of intelligent scientific research.

THE TOMATO AS AN ANTISCORBUTIC

Several circumstances recently have conspired to direct attention to the problem of antiscorbutics. Scurvy has made its appearance among various groups of persons abroad because of conditions directly or indirectly brought about by the war. The shortage of antiscorbutic green foods in certain areas has emphasized the need of preventive measures that belong at present entirely within the realm of diet. The difficulties of transportation and of food conservation have suggested the employment of products preserved by desiccation or other methods in order that the seasons of plenty may serve the periods of scarcity. Valued antiscorbutics like orange juice have become too expensive for use among the less-well-to-do classes. In view of this situation it is not surprising to find vigorous efforts displayed here and abroad in the attempt to discover "ways and means" out of the impending difficulties. Some of the results achieved have already been outlined in The Journal.[2] Side by side with the juice of the lemon and the swede, the tomato is now worthy of ranking, according to the simultaneously published observations of Hess and Unger[3] at the Bureau of Laboratories in the New York City Department of Health, and of Givens and McClugage[4] at the University of Rochester. Hess and Unger have actually administered canned tomatoes to infants who were receiving pasteurized milk, substituting it in the dietary for orange juice, which has become increasingly expensive. The amount given to babies 3 months or more of age was 15 c.c., half this quantity being given daily to younger infants. The tomatoes have been uniformly well tolerated throughout the summer by babies as young as 1 or 2 months of age. The fact that both the New York and the Rochester investigators found that the methods of preservation—canning and drying, respectively—do not entirely deprive the tomato of antiscorbutic potency gives a welcomed addition to the list of perennially available food products that can be depended on to protect infants, as well as adults likewise depending on restricted diets, from the danger of scurvy.

Increase in Deaths from Illuminating Gas.—The records of the New York City Health Department show that for the first eight weeks of 1918 there have been 232 deaths from illuminating gas, as against 145 during the corresponding period of 1916, an increase of eighty-seven deaths.

Association News

THE ATLANTIC CITY SESSION

Advisory Committee on Scientific Exhibit—Desirability of Early Application for Space

The following Advisory Committee on Scientific Exhibit has been appointed for the Atlantic City Session: Harlow Brooks, New York; A. S. Warthin, Ann Arbor; George Dock, St. Louis; C. C. Bass, New Orleans; Walter B. Cannon, Boston; L. B. Wilson, Rochester, Minn.; William M. L. Coplin, Philadelphia; James T. Case, Battle Creek, Mich.; Joseph C. Bloodgood, Baltimore; E. R. LeCount, Chicago; Oscar Klotz, Pittsburgh, and F. P. Gay, Berkeley, Calif.

The Scientific Exhibit will occupy the pavilion of the new steel pier. Applications for space may be secured from the Director of the Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago. In order that suitable plans may be made, it is desirable that applications be submitted as early as possible.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending March 7, the Medical Corps contained 21,103 officers, a decrease from the previous week of 442. The Medical Reserve Corps contained 876 officers. The total number of medical officers discharged since the beginning of the war is 12,458.

Medical Veterans of the World War

Physicians who rendered service to the government during the world war either as officers of the Medical Corps of the U. S. Army, of the U. S. Navy or of the U. S. Public Health Service; as contract surgeons in the U. S. Army or acting assistant surgeons of the U. S. Public Health Service; as medical members of Local Boards, or members of the Medical Advisory Boards, are eligible to membership in the Medical Veterans of the World War. As previously announced, Col. F. F. Russell, Army Medical School, Washington, D. C., is secretary of the temporary organization. Those interested should write to him for forms for making application for membership. With these applications there should be forwarded $1 in payment of the first year's annual dues.

Distinguished Service Medal Awards

By direction of the President, the Distinguished Service Medal is awarded for exceptionally meritorious and conspicuous service to the following named officers:

EDWARD L. MUNSON, Brig.-Gen., M. C., U. S. Army, for exceptionally meritorious and conspicuous service. He developed the scheme of field training for officers and enlisted men of the Medical Department, directed the organization and administration of the medical officers' training camps, and organized and administered the Morale Branch of the General Staff.

THEODORE C. LYSTER, Col., M. C., U. S. Army, for exceptionally meritorious and conspicuous service; for duty rendered in the Office of the Surgeon-General as Chief, Air Service Division.

Prisoners Released

The following officers, who have been prisoners in Germany, are reported to have been released from German camps and hospitals and returned to France: Frank K. Miller, Madera, Pa., and Abraham Julius Gordon, Newark, N. J., Lieuts., M. C., U. S. Army.

Wounded Severely

The following officers are reported in the *Official Bulletin* as having been wounded severely: Raymond C. Turck, Lieut.-Col., M. C., U. S. Army, Jacksonville, Fla.; Horatio N. Jackson, Major, M. C., U. S. Army, Burlington, Vt.; Russell Rulo Heim, Capt., M. C., U. S. Army, Grantsburg, Wis., and Ernest J. Hoover, Altoona, Pa.; Claude Edwin Snyder, Altoona, Pa.; Wesley J. C. Wiemers, Houston, Texas, and Lloyd Edward Wurster, Linden, Pa., Lieuts., M. C., U. S. Army.

Wounded Slightly

The following officers are reported in the *Official Bulletin* to have been slightly wounded: Walter J. Johnson, Frankewing, Tenn.; Edward J. Kennedy, Milford, Ohio; David Sussler, Dorchester, Mass.; Joseph K. Surls, Brookline, Mass.; Milton C. Wiggins, Cottagegrove, Tenn.; Schuyler Colfax Harbour, St. Louis, Mo.; Lester L. Powell, Saco, Mo.; Alfred M. Bergstein, Pottsville, Pa.; Clarence H. Denser, Xenia, Ohio, and Eugene Rank Cocke, Asheville, N. C., Lieuts., M. C., U. S. Army, and Harold F. Park, Boston, Mass., Capt., M. C., U. S. Army.

Wounded, Degree Undetermined

The following officers are reported in the *Official Bulletin* as having been wounded (degree undetermined): Adolph Francis Srb, Dodge, Neb.; William L. Hanson, Belleville, Ill.; Lorens A. Haug, Canton, S. C.; Edwing E. Miller, *Nashville, Tenn.; Eugene Henry McCaffrey, Maquoketa,* Iowa; Alton W. Davis, Mitchell, Ga.; Farrar B. Parker, New Orleans; John Browning Baldwin, Marshall, Texas, and John Logan Steffy, Pittsburgh, Lieuts., M. C., U. S. Army, and Harold H. Freund, New York; Frederick R. Hickey, Manhattan, Kan.; John Armstead Winstead, Nashville, N. C., and Chester L. Barry, Oxford, Pa., Capts., M. C., U. S. Army.

Military Cross Awards

King George V, March 5, conferred the Military Cross on the following medical officers: Edward A. Christofferson, Capt., M. C., U. S. Army, Chicago; Alexander J. Gillis, Baltimore, and Robert B. MacDuff, Flint, Mich., Lieuts., M. C., U. S. Army; William L. Smith Capt., M. C., U. S. Army, Toledo, Ill., and Frederick B. Little, Capt., M. C., U. S. Army, Uniontown, Pa., for bravery under fire.——The Military Cross was awarded to Thomas L. Doyle, Capt., M. C., U. S. Army, Tremont, Pa., for "great gallantry and devotion to duty in dressing the wounded under continuous shell fire for seven days during the battle of Saint Quentin Canal, said duty being performed in open with no protection, being exposed continually to enemy machine gun and shell fire."

Receives Medal of Honor

Clarence C. Burlingame, Lieut., M. C., U. S. Army, South Manchester, Conn., on duty with the American Red Cross in France was decorated, Dec. 24, 1918, by the French government with the Medal of Honor of the first class. The diploma accompanying the medal reads: "In the name of the President of the Republic, the minister of war bestows a Medal of Honor in vermeil on Dr. Burlingame. He has given his most precious services for the organization and installation of numerous medical formations where French wounded have been taken care of, especial mention being made for work during the grip epidemic. Dr. Burlingame is authorized to wear this medal suspended by the tricolor ribbon equally divided. This diploma has been delivered in order to perpetuate in his family and among his fellow citizens the memory of his honorable and courageous conduct."

Victoria Cross Awarded

The British military authorities have awarded the Victoria Cross, the highest appreciation for bravery in their power to bestow, to Bellenden Seymour Hutcheson, Capt., M. C., U. S. Army, Mound City, Ill. Captain Hutcheson was attached to the 97th Canadian Battalion, and on going to the battle front was appointed medical officer of the 75th (Toronto) Battalion of the first Central Ontario Regiment. The official record states that the award was bestowed on him "for most conspicuous bravery and devotion to duty, Sept. 2, 1918, when under most intense shell, machine gun and rifle fire, he went through the Quéant-Drocourt support line with his battalion. Without hesitation and with utter disregard of personal safety he remained on the field until every wounded man had been attended to. Captain Hutcheson performed many similar gallant acts, and by his coolness and devotion to duty many lives were saved."

Win War Crosses

George Harrison, Capt., M. C., U. S. Army, Ashland, Wis., on duty overseas, was awarded the Croix de Guerre at Toul by French authorities for extraordinary bravery under fire.——Bertram Tremblay, Lieut., M. C., U. S. Army, Manchester, N. H., has been awarded the Croix de Guerre.——Ivor D. Fenton, Capt., M. C., U. S. Army, on duty with the 315th U. S. Infantry, has been recommended for the Croix de Guerre for gallant service in the Argonne Forest.——Robert J. Lawler, Major, M. C., U. S. Army, Niagara Falls, N. Y., on duty with the Fifth Regiment, has been awarded the Croix de Guerre.——David Reynolds Morgan, Capt., M. C., U. S. Army, Edwardsville, Pa., three times cited for bravery, has been awarded the Croix de Guerre.——C. P. Price, Lieut. M. C., U. S. Army, Mercer, Ky., on duty with the Seventeenth Field Artillery, Second Division, has been awarded the Croix de Guerre for conspicuous bravery at the battle in the Blanc Mont sector.

Abandonment of Army Hospitals

With the abandonment of a number of Army camps and the concentration of sick and wounded soldiers in city hospitals, the Surgeon-General of the Army is taking steps to discontinue several camp hospitals. The base hospitals at Camps Cody, N. M.; MacArthur, Texas, and Hancock, Ga., and General Hospitals No. 18, at Waynesville, N. C., and No. 23 at Hot Springs, N. C., are slated for abandonment at an early date. In addition, it is also proposed to discontinue base hospitals at Camps Greene, N. C.; McClellan, Ala.; Sevier, S. C.; Wheeler, Ga.; and General Hospitals No. 15, at Corpus Cristi, Texas; No. 17, at Markleton, Pa.; No. 37, at Madison Barracks, N. Y., and Debarkation Hospital No. 52, at Richmond, Va. The capacity of the hospital at Camp Kearney, Calif., will be reduced to 500 beds. The Surgeon-General has recommended that General Hospital No. 33 at Fort Logan H. Roots, Ark., be changed to a post hospital, and that the post hospitals at Edgewood, Md., Arsenal, Eustis and Humphreys, Va., be made camp hospitals. No more overseas patients will be sent to any of the foregoing hospitals, except Camp Kearney.

Weekly Bulletin, A. E. F.

(Feb. 3, 1919)

PROMOTIONS

As stated last week, on Jan. 16, 1919, the chief surgeon forwarded [to G. H. Q. through headquarters, S. O. S.] a list of recommendations for promotion embracing eighty-five lieutenant-colonels to grade of colonel, 282 majors to grade of lieutenant-colonel, 932 captains to grade of major, and 2,457 lieutenants to grade of captain. In sending this list the comment is made that it is certain that many of the medical officers serving with the British have not received the promotion to which the law and the character of their services have entitled them. They have failed to get their merited promotion because in addition to the obstacles, delays and accidents which have been incidental to the history of promotions in the A. E. F. there was the added delay of mail communication with the B. E. F., and the great difficulty in getting from the 900 or more officers on duty with the British the reports of character of service and qualifications on which the roster was based which determined their promotion, up to and including major.

The necessity for making promotions in the Medical Corps of the A. E. F. has been especially urgent because most of the reserve corps officers were commissioned in the lowest grade (first lieutenant), which was originally the only one, including men who had been fifteen or twenty years in practice. It was the intention of the Surgeon-General to give these men prompt promotion as soon as their fitness for positions of increased responsibility was demonstrated, but the machinery for promotion has presented unexpected difficulties in the A. E. F., and therefore we find the proportion of lieutenants to be about 60 per cent. instead of the 14 per cent. provided by law.

Very few promotions were made during the first ten months of the existence of the American Expeditionary Forces. Those proposed by the chief surgeon were, as a rule, disapproved on the ground that definite and methodical scheme of promotion, which would, as nearly as possible, do justice to all, should be presented before the commander-in-chief would be willing to make promotions except in very exceptional cases. Such a scheme was finally worked out and presented to the commanding general on May 17, 1918.

This plan was for the application of the principle of selection for the grade of captain and major by means of a roster on which each man took his place according to a roster number obtained by the addition of certain factors which were:

1. Age, which represents in a general way professional experience.
2. Military service, which represents military experience.
3. Character of service and special qualifications, which are given a numerical value in accordance with a special report made in each case by the immediate superior officer.

This scheme was approved in principle, May 31, and finally approved by the commander-in-chief, June 27. The first list was forwarded on June 15 and five others in July. A number of other lists were forwarded in August. All lists after September 4 were held at general headquarters for action there under G. O. 78. Promotions of lieutenants, however, were not cabled to Washington but sent by courier and even in the case of those of higher grades the inevitable delays in the War Department made the process of getting through a promotion very slow. The entire summer passed without any promotions being received by medical reserve officers except one group on June 6. It was recently discovered that the list which was forwarded from this office on August 21 and sent by cable to the adjutant-general on September 2 was apparently never received but apparently lost in the cable office. This list contained the names of fifty-four captains recommended for promotion to major. A letter was recently written requesting that these nominations, which received the approval of the commander-in-chief more than four months ago, be now published as promotions of that date.

The chief surgeon was informed on September 4 by the Adjutant General, A. E. F., that a new War Department General Order on the subject of promotions (G. O. 78, W. D., Aug. 22, 1918) was enroute from the United States. It was hoped that this order, which authorized promotions to be made by the commander-in-chief up to and including the grade of colonel, subject to confirmation by the War Department, would greatly simplify and expedite promotions. This expectation was, however, disappointed because the opinion was advanced that in order to determine the question of whether vacancies existed an approved table of organization was necessary. It was then pointed out by the chief surgeon that as the law provided that there should be a certain proportion of medical officers in each grade, the number of vacancies in each grade could be readily determined by applying the proportions to the total number of medical officers in the A. E. F. The opinion was then expressed by the Judge Advocate's Office that the Surgeon-General should be a party to this arrangement in order that the legal proportions in each grade should not be exceeded for the Medical Department with the other forces. The question of the applicability of General Order 78 to the Medical Department was finally referred to the War Department by cablegram of the commander-in-chief dated October 11, which was replied to by the chief of staff on October 19, stating it *did not apply* to officers in the Medical Department. It is understood that the negative in this cable was an error in coding. When the matter was again presented by the commander-in-chief on October 28, for reconsideration he was informed by cable of November 5, that his request for authority to promote medical officers was approved. The chief surgeon was informed of this decision on November 7, but four days later the armistice was signed and stopped all temporary promotions. During this short period, however, 672 medical, thirty-two sanitary, and fifty-three veterinary officers were promoted.

MEDICAL OFFICERS, U. S. NAVY, RELIEVED FROM ACTIVE DUTY

CALIFORNIA

Los Angeles—Crispin, E. L.
Palo Alto—Williams, T. M.
San Francisco—Vogel, A. B.

DISTRICT OF COLUMBIA

Washington—Crawford, C. B.

Ohio

To Camp Dix, N. J., base hospital, from Camp Meade, Major R. H. BIRGE, Cleveland.

To Camp Sherman, Ohio, base hospital, from Camp Custer, Lieut. R. H. McKAY, Akron.

To Camp Zachary Taylor, Ky., base hospital, from Camp Shelby, Capt. C. MULKY, Warrensville.

To Columbus Barracks, Ohio, from Camp McArthur, Lieut.-Col. E. F. McCAMPBELL, Columbus; from Fort Riley, Lieut. E. C. NEHLS, South Charleston.

To Detroit, Mich., from Camp McClellan, Lieut. R. E. SINKEY, Toledo; from Camp Upton, Capt. M. A. WAGNER, Lima.

To Fort Benjamin Harrison, from Fort Oglethorpe, Lieut. H. H. WILLIAMS, Dayton.

To Fort McHenry, Md., from Camp Dix, Lieut. C. H. MOSES, Youngstown.

To Fort Sheridan, Ill., from Camp Dix, Capt. H. K. YAGGI, Salem; from Camp Sheridan, Capt. D. W. PHILO, Fremont; from Fort Oglethorpe, Lieut. W. M. LEONARD, Cleveland.

To Fort Snelling, Minn., from Camp Sherman, Lieut. J. B. DOYLE, Cincinnati.

To San Francisco, Calif., from Fort Riley, Lieut. H. W. WILLIAMSON, Toledo.

To Washington, D. C., Surgeon-General's Office, from Cape May, Major J. M. INGERSOLL, Cleveland.

Oklahoma

To Fort Des Moines, Iowa, from Fort Riley, Lieut. J. E. HEATLEY, Carmen.

To Fort Sheridan, Ill, from Camp Sheridan, Capt. O. HOVENDEN, El Reno.

To Wiliamsbridge, N. Y., from Camp Dix, Capt. G. D. McLEAN, Oklahoma City.

Oregon

To Camp Lewis, Wash., from Camp Meade, Lieut. G. S. NEWSOM, Prineville.

To Fort Sam Houston, Texas, base hospital, from Camp Kendrick, Capt. P. J. KEISER, North Bend.

To Riverside, Calif., March Field, from Vancouver Barracks, Capt. T. H MILLER, Eugene.

Pennsylvania

To Biltmore, N. C., from Camp Greene, Major C. P. BROWN, Glen Olden.

To Camp Abraham Eustis, Va., base hospital, from Camp Greene, Capt. G. G. KALMUTZ, Wilkes-Barre; from Camp McClellan, Lieut. F. B. BLOCK, Philadelphia.

To Camp Sherman, Ohio, base hospital, from Williamsbridge, Major J. R. V. WOLFE, Norristown.

To Camp Wadsworth, S. C, base hospistal, from Camp Sheridan, Lieut. J. H. GOLDSTEIN, Pittsburgh.

To Cape May, N. J., from Camp Dix, Major G. H. DORRANCE, Philadelphia.

To Fort McHenry, Md., from Camp Dix, Lieut. J. W. BRANSFIELD, Philadelphia.

To Hoboken, N. J., from Fort McPherson, Lieut. W. P. DODDS, Pittsburgh; from Northeastern Department, Lieut.-Col. J. F. EDWARDS, Pittsburgh.

To Lakewood, N. J., from Rockefeller Institute, Capt. E. A. CAMPBELL, Chester.

To Pittsburgh, Pa., from Camp Dix, Lieut. W. E. GARDNER, Pittsburgh; from Camp McClellan, Capt. H. S. FISH, Sayre.

To Rockefeller Institute for instruction in the treatment of infected wounds, and on completion *to Camp Meade, Md.*, base hospistal, from Camp Hancock, Lieut. A. H. JAHN, Pittsburgh. On completion *to his proper station*, from Fort McHenry, Lieut. W. F. WHITE, Wellsboro.

To Washington, D. C., Surgeon-General's Office, from Camp Pike, Capt. R. V. ROBINSON, Pittsburgh.

The following order has been revoked: *To Washington, D. C.*, from Camp Dix, Capt. J. J. SINGER, Greensburg.

Rhode Island

To Army Medical School for instruction, from Camp Dix, Major M. S. DANFORTH, Providence.

To Philadelphia, Pa., from Camp McClellan, Lieut. E. W. MULLIGAN, Providence.

South Carolina

To Boston, Mass., from Camp Sevier, Lieut.-Col. C. E. FRONK.

To Camp Shelby, Miss., from Camp Wadsworth, Capt. T. J. PEAKE, Clinton.

To Newport News, Va., from Camp McClellan, Lieut. T. R. LITTLEJOHN, Sumter.

South Dakota

To Fort Des Moines, Iowa, from Camp Upton, Capt. L. Z. FLETCHER, Montrose.

Tennessee

To Fort McDowell, Calif., to examine the command for nervous and mental diseases, from Fort Leavenworth, Capt. J. P. SCHELL, Nashville.

To Fort McPherson, Ga., from Fort Leavenworth, Capt. G. A. HATCHER, Nashville.

To Fort Oglethorpe, from Camp Dix, Capt. C. P. EDWARDS, Kingsport.

To Newport News, Va., from Camp McClellan, Capt. M. G. BUCKNER, Nashville.

To Oteen, N. C., from Camp Hancock, Capt. J. O. WOODS, Newport.

To Rockefeller Institute for instruction, and on completion *to his proper station*, from Fort McHenry, Lieut. J. H. REVINGTON, Chattanooga.

Texas

To Camp Bowie, Texas, from Camp Dodge, Capt. D. C. WYLIE, Aspermont. Base hospital, from Fort Des Moines, Capt. W. C. DURINGER, Fort Worth.

To Camp Grant, Ill., base hospital, from Camp Dix, Lieut. C. B. YOUNG, Jr., Houston. *To examine the command* for nervous and mental diseases, from Camp Logan, Lieut. F. O. CALAWAY, Austin.

To Camp Lee, Va., base hospital, from Camp Logan, Lieut. R. W. DUNLAP, Palestine.

To Camp Logan, Texas, to examine the command for nervous and mental diseases, from Camp Gordon, Lieut. C. W. CASTNER, Terrell.

To Camp Travis, Texas, base hospital, from Camp Lewis, Major I. L. McGLASSON, Waco.

To Fort McHenry, Md., from Camp Logan, Capt. H. L. WARWICK, Fort Worth.

To Fort McPherson, Ga., from Camp Dix, Lieut. W. M. DICKENS, Greenville.

To Fort Sam Houston, Texas, from Camp Dodge, Major C. H. BYARS, Brownsville. Base hospital, from Camp Hancock, Lieut. W. L. ASKEW, Amarillo; from Camp Wheeler, Lieut. J. V. HOPKINS, Victoria.

To Houston, Texas, Ellington Field, from Camp John Wise, Major J. DIBBLE.

To Middletown, Pa., from Camp Dix, Capt. O. P. GOODWIN, Lamasco.

The following orders have been revoked: *To Camp Crane, Pa.*, from Hoboken, Lieut. W. H. SMITH, Hondo. *To Camp Kelly*, Texas, Lieut. R. P. GLENN, Abilene.

Vermont

To Camp Sheridan, Ala., base hospital, from Camp Dix, Lieut. J. D. THOMAS, Pownal.

To Camp Zachary Taylor, Ky., base hospital, from Camp McClellan, Capt. R. B. THOMAS, Enosburg Falls.

To Hoboken, N. J., from Mays Landing, Lieut. H. L. TILLOTSON, Groton.

To Plattsburg Barracks, N. Y., from Camp Jackson, Capt. A. D. FINLAYSON, Burlington.

Virginia

To Camp Abraham Eustis, Va., from Camp Lee, Major G. C. BEACH, Jr.

To Camp Lee, Va., base hospital, from Camp Dix, Major R. P. BELL, Staunton.

To Camp Meade, Md., base hospital, from Camp Wadsworth, Lieut. W. H. CRAIG, Richmond.

To Fort McHenry, Md., from Camp Dix, Capt. M. C. LILE, University.

To New Haven, Conn., from Camp Abraham Eustis, Major A. FREER.

To Philadelphia, Pa., from Camp Sevier, Lieut. B. E. STRODE, Amherst.

To report to the commanding general, Southern Department, from Camp Logan, Lieut. A. H. DEEKENS, Lynchburg.

Washington

To Alcatraz, Calif., from Fort Leavenworth, Major A. P. CALHOUN, Seattle.

To Americus, Ga., Souther Field, from Vancouver Barracks, Lieut. H. T. DOUST.

To Army Medical School for instruction, from Camp Dix, Major C. F. EIKENBARY, Spokane.

To Camp John Wise, Texas, from Vancouver Barracks, Major A. H. LEHMAN.

To Camp Lewis, Wash., from San Francisco, Major W. N. KELLER, Tacoma.

To Camp Zachary Taylor, Ky., base hospital, from Camp Dix, Lieut. W. C. KINTNER, Seattle.

To Dallas, Texas, Love Field, from Vancouver Barracks, Lieuts. H. M. ANDREW, S. G. ODOM.

West Virginia

To Jefferson Barracks, Mo., from Camp Abraham Eustis, Lieut. F. W. WIEHE, Wheeling.

To Walter Reed General Hospital, D. C., from Camp Dix, Capt. C. S. COWIE, Martinsburg.

To Washington, D. C., Surgeon-General's Office, from Kingsport, Lieut. S. W. BULL, Spencer.

Wisconsin

To Camp Sheridan, Ala., base hospsital, from Camp MacArthur, Capt. O. A. NELSON, Park Falls.

To Camp Upton, N. Y., base hospital, from Fort Porter, Capt. S. G. PAKE, Haywood

To Chicago, Ill, from Camp McClellan, Lieut. D. H. WITTIE, Hartford.

To Denver, Colo., from Camp A. A. Humphreys, Capt. L. H. FLANCHER, Lomira.

To Fort Des Moines, Iowa, from Camp MacArthur, Capt. F. W. APLIN, Waukesha.

To Washington, D. C., Surgeon-General's Office, from Camp Dix, Major R. H. IVY, Milwaukee.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

State Medical Society Meeting.—The Medical Society of the State of California will hold its annual meeting at Santa Barbara, April 15-17.

Expenditures for Influenza.—Dr. William C. Hassler, city health officer of San Francisco, reported to the supervisors' finance committee that $35,292 had been expended of the $50,000 provided for the relief of needy sufferers during the influenza pandemic.

Conviction Sustained.—The district court of appeals, February 18, confirmed the conviction of Dr. William S. Card, San Francisco, on the second degree murder charge coming out of an alleged illegal operation performed May 21, 1918. Dr. Card was convicted in the superior court, July 9, 1918, and sentenced to imprisonment for an indeterminate term.

Personal.—Dr. Morris Herzstein, San Francisco, sailed for Europe, March 8, on the steamer *George Washington*, to make a study of a number of new surgical problems in the hospitals in London and Paris.——Dr. William C. Hassler, city health officer of San Francisco, has been appointed superintendent of the San Francisco Hospital during the absence of Dr. Richard G. Brodrick, who has been granted leave of absence to supervise the construction and equipment of the new $2,000,000 hospital for Alameda County.——Dr. T. d'Arcy M. Quinn has been appointed city physician of San Francisco.

ILLINOIS

Encephalitis Lethargica.—This disease has now been made notifiable by the Chicago health department and also by the state department of health. One death has occurred at Marseilles, and one in the Children's Memorial Hospital in Chicago.

Smallpox at Salem.—Smallpox is reported to have broken out at Salem, Marion County, the infection being conveyed by the principal of the school, who did not know that he had smallpox. Dr. J. A. Keppleman of the state department of health, Springfield, has been sent to Salem to take charge of the situation.

Personal.—John Wesley Tope, Capt., M. C., U. S. Army, Oak Park, who went overseas with the Thirteenth Engineers, returned to the United States, March 5.——Robert Nelson Lane, Capt., M. C., U. S. Army, Gibson City, returned from overseas, March 5.——Dr. Charles H. Franz, Aurora, after thirty years of practice in Illinois, during which time he was at one time assistant superintendent of the Elgin State Hospital and president of the Fox River Medical Society, has moved to San Francisco, where he is assistant surgeon in the United States Public Health Service.

Influenza Survey.—The department of public health of Illinois during February conducted a house to house canvass of the influenza situation in selected localities in Illinois, principally in cities whose populations were composed chiefly of miners and their families. The investigation disclosed that the disease was more prevalent among children than adults, contrary to the general impression, and that the duration of the disease among the children was from three to five days, as against from seven to eight days among adults. The mortality among the children was also found to be small, while in adults it was much larger. In some communities from 70 to 75 per cent. of the population had had the disease.

Speedway Hospital.—The final plans for taking over by the United States Public Health Service of the Speedway Hospital have been perfected, and it is expected that the institution will be ready for occupancy by July 1. The revised plans include the changing of the large wards into smaller separate units, and this will involve an additional expense of about $500,000. The scope of the project is much larger than that of a hospital. It is to be a national medical center where the various activities of the United States Public Health Service will unite, and from which the future work of the service of sanitation and hygiene will be carried on. The hospital will contain more than 1,500 beds, and there will also be lecture halls, an extensive museum of hygiene, and sufficient space to admit the segregation of diseases and to afford place for special study.

Chicago

Improvements at the Marine Hospital.—The improvements at the United States Marine Hospital, for which an appropriation of $110,000 was recently made, include a residence for the surgeon to cost $10,000; officers' quarters to cost $20,000, and quarters for attendants and nurses to cost $80,000.

Personal.—James J. McGuinn has returned after six months' work with the American Red Cross in France and Germany. ——Maurice L. Goodkind, Major, M. C., U. S. Army, who is on duty in France with the Fifty-Third Hospital Unit, has been promoted to the rank of lieutenant-colonel.——Eugene Cary, Capt., M. C., U. S. Army, who has been on duty with the Royal Air Forces, has returned to this country.——John Edward Kelley, Capt., M. C., U. S. Army, who has been on duty in France, has returned to Chicago.——Gustavus M. Blech, Major, M. C., U. S. Army, who went overseas as assistant division surgeon of the 33d Division, has been promoted to lieutenant-colonel, M. C., U. S. Army, and is in command of U. S. Army Base Hospital No. 208, which is located near Bordeaux. The hospital has accommodation for 4,000 patients, covers 65 acres of ground, and contains more than 100 barracks and an administration building.——Frederick A. Besley, Lieut.-Col., M. C., U. S. Army, has returned from California.

IOWA

Emergency Hospitals Closed.—The Red Cross emergency hospitals at Storm Lake and Marshalltown, which were opened during the influenza pandemic, have been closed.

New Laboratory for Sanatorium.—A bill calling for an appropriation of $25,000 for a laboratory for the Oakdale Sanatorium near Iowa City has been passed by the state senate. The new building will be a two story, fire-proof structure.

New Officers.—At the annual meeting of the Muscatine County Medical Society held in Muscatine, February 27, the following officers were elected: president, Dr. D. Powers Johnson; vice president, Dr. William H. Johnston, and secretary-treasurer, Dr. William W. Potter, all of Muscatine.

Children's Hospital Ready.—The Hospital for Crippled Children connected with the University of Iowa, Iowa City, is now ready to receive patients and will soon be formally dedicated. At present there are eighty-five patients waiting in the Perkins Ward of the University Hospital. The new hospital will accommodate more than 100 patients.

Personal.—Dr. David E. Beardsley has been appointed associate district surgeon of the Chicago and Northwestern System, at Cedar Rapids.——Daniel J. McCarthy, Major, M. C., U. S. Army, Davenport, a member of the American Red Cross Commission in Serbia, has been given the highest decoration of the Serbian government for his work among soldiers and refugees.——Edwin C. Yoder, Lieut. M. C., U. S. Army, Iowa City who has been on duty with the Medical Corps in France, has returned home.——Dr. John H. Peck, Des Moines, was elected president, and Drs. Herbert R. Sugg, Clinton, Gilford H. Sumner, Des Moines, and William H. Bickley, Waterloo, were elected directors of the Iowa Tuberculosis Association, at the annual meeting held in Des Moines, February 18.——Dr. Emil O. Ficke, Capt., M. C., U. S. Army, Davenport, on duty with the 90th Division, American Expeditionary Forces in France, has returned and resumed practice.——Dr. Walter A. Sternberg, Mount Pleasant, was seriously injured in a collision between automobiles, February 4.

Hospital Authorities Defended.—Judge Charles W. Mullan of the District Court of Iowa recently decided a question of interest to physicians relative to the power of the boards of health to require privately owned general hospitals to accept patients suffering from contagious diseases, which had reached the stage of epidemic in the city of Waterloo. The particular epidemic in question was influenzal pneumonia. The health authorities of Waterloo, acting under the statute which gives municipalities the power of protecting the general welfare of communities by the passage of suitable ordinances and resolutions, passed a resolution declaring the existence of public peril, and sought enforcement of the resolution by tendering to the hospital patients suffering from the disease, and on the refusal of the hospital to receive these patients, brought action for the affirmative equitable relief of enforcement. The hospital authorities challenged the power of the board of health, and challenged its acts further on the grounds that in the enforcement it amounted to taking private property without compensation, and furthermore that the regulation was unreasonable. The court decided the case without reference to the reasonableness, but found under the law that the board of health was without any power such as it proposed to exercise. The result was unconstitutional because it amounted to the taking of private property without compensaton, and held that in any event no decree in such a case could be enforced because of the fact that it required personal services of nurses and attendants which would render the court powerless to execute its decree if rendered.

MARYLAND

Gift to Blinded Soldiers.—Soldiers blinded in war, who are receiving vocational training at United States Hospital No. 7, Evergreen Junior, have received a gift of nearly $3,000 from the Baltimore committee of the Woman's Homeopathic Base Hospital Unit.

Personal.—Dr. Elizabeth Hurdon, Baltimore, who was on the medical staff of the British army behind the lines at Saloniki, and Dr. J. Preston Maxwell, engaged in medical work in China during the various plagues for the last twenty years, both members of the staff of the Johns Hopkins University, gave interesting accounts of their experiences, March 7, at Osler Hall before the Baltimore City Medical Society. ——Dr. William S. Thayer, Baltimore, who returned recently to this country after serving with the United States Medical Corps with the rank of brigadier-general, gave a graphic account of his sojourn in Russia during the revolution of 1917, to the students and nurses of Johns Hopkins Hospital, March 8.

Plans for Health Center.—Plans for the establishment of a health center in northwest Baltimore in connection with the new bureau of child hygiene and infant mortality were discussed at a special meeting of the board of estimates held during the past week. The city health department was allowed a physician at $1,800 a year, with the understanding that he would devote all of his time to the work. The department was also allowed three obstetric nurses at $1,100 a year each, three social service nurses at the same pay, a dispensary clerk at $900, a service woman for a day nursery at $500, and $10,800 for equipment. The board also approved a recommendation from Dr. Mary Sherwood, head of the bureau, that $8,000 be set aside for the employment of eight nurses for child welfare work where most needed, especially in the prevention of summer complaint and pneumonia, and that $2,500 be set aside for the immediate development and running expenses of a day nursery for babies in the general neighborhood of existing city health agencies.

MASSACHUSETTS

Personal.—Harvey Cushing, Col., M. C., U. S. Army, Brookline, director of Base Hospital Unit No. 5, the second Harvard Medical Unit to go overseas, reached New York, February 19, on the U. S. S. *Canopic* from Brest after twenty-one months' service abroad.

Unregistered Practitioner Fined.—Mrs. Minnie Buchsegger, Attleboro, a chiropractor, charged with practicing medicine without registration, is said to have waived exemption in the district court, February 19, and to have been fined $600. She appealed from this decision and was held in bond of $1,000.

MINNESOTA

Influenza.—Deaths in Minnesota during 1918 numbered 31,133, as compared with 23,615 in 1917. Influenza was responsible for 7,260 deaths in 1918. More than 125,000 influenza cases were reported.

Certificates in Public Health Nursing.—The first class of thirteen nurses in the course in public health nursing under the direction of the Minnesota Public Health Association and the University of Minnesota received their certificates at the end of the four months' course, February 13. The course is for the benefit of graduate nurses from accredited training schools and senior nurses in training. The second class began its instruction, March 5.

Personal.—S. Marx White, Major, M. C., U. S. Army, Minneapolis, chief of the medical service in Base Hospital No. 26, spoke at the noonday meeting of the Hennepin County Medical Society, February 26, on "Some Medical Lessons from the War."——Dr. Walter L. Mattick of Deerwood Sanatorium held a free tuberculosis clinic at Aitkin, February 15. ——In the suit brought against Dr. Daniel C. Darrow, Moorhead, by Mrs. P. H. Sorenson, for assault while under medical treatment, in which $20,000 damages were sought, the jury is said to have returned a verdict giving the plaintiff $3,000.—— Warren A. Dennis, Lieut.-Col., M. C., U. S. Army, St. Paul, who was on duty with Base Hospital No. 88, at Langres and Sovenay, France, for five months, returned on the U. S. S. *Rotterdam,* which arrived in New York, February 17.

NEW YORK

Watertown to Have Full-Time Health Officer.—Watertown has appropriated $3,000 for the services of a full-time health officer and $600 for a part-time public health nurse.

Society Opposes Health Insurance.—The Albany County Medical Society, March 4, after a four hours' debate at a special meeting, went on record as opposing any bill embodying the scheme of compulsory health insurance.

Health Department Reunion.—The twelfth annual reunion of the Health Department of Buffalo was held, February 25, and was attended by more than 200 members of the department, former members, and their friends. Dr. Edward Durney was chairman of the occasion.

Chiropractor Convicted.—George N. Devinny, a chiropractor of Albany, is said to have been found guilty of violating the public health law by practicing medicine without a license, and to have been sentenced, March 2, to imprisonment for ten days and to pay a fine of $500. Devinny stated that he had been convicted in 1915 on a similar charge.

New York City

Harvey Society Lecture.—The sixth lecture of the Harvey Society series will be given by Dr. Yandell Henderson at the New York Academy of Medicine, March 29, at 8:30 p. m., on "Physiology of the Aviator."

Another Medical College Admits Women.—New York University and Bellevue Hospital Medical College will admit women on the same basis as men and with full privileges of the college, in September, and will grant them the degree of Doctor of Medicine on graduation. Medical degrees have just been conferred on seventy-seven students who finished their courses three months earlier than usual, owing to the war emergency program adopted last year.

Appeal for Funds to Continue Treatment of Children.—The New York Committee on After-Care of Infantile Paralysis, whose headquarters are at 289 Fourth Avenue, is making an appeal for $75,000, so that the treatment of children who have not yet recovered may be continued. A summary of the work done by the committee shows that 8,720 children have been cared for and 2,913 braces furnished. The entire receipts have been $280,852, of which $278,321 has been disbursed.

Report on Drug Addicts.—James A. Hamilton, commissioner on correction, in his annual report on drug addicts, shows that 240 men and thirty-two women were committed by the courts during the past year as drug users. Of these, 114 men and sixteen women had never been convicted of crime. Commissioner Hamilton recommends that all drug cases should be committed to a correctional institution instead of to hospitals for treatment, because it is too easy for the addict to get out of a hospital.

Personal.—Dr. Samuel W. Lambert, dean of the College of Physicians and Surgeons in the City of New York for fifteen years, and professor of clinical medicine, has resigned from the faculty of that institution, to take effect on June 30.—— Dr. Frederic Huntington Coerr has returned from foreign service and will resume his practice.——Herbert L. Celler, Major, M. C., U. S. Army, recently arrived in this country after service with the Mount Sinai Hospital Unit in France. ——Harold Neuhof, Lieut., M. C., U. S. Army, who has been overseas since May, 1917, has returned to civil life.——David Lothringer, Capt., M. C., U. S. Army, who has been in the service with the American Expeditionary Forces as surgeon of the Seventh Trench Motor Battalion, has been mustered out of the service.

Annual Report of Mount Sinai Hospital.—The annual meeting of the Society of Mount Sinai Hospital was held, March 3, at which time addresses were made by Col. Howard Lilienthal and Major Edwin Beer, who have recently returned from Base Hospital No. 3, the Mount Sinai Unit, which served in France. It is the intention of the authorities to resume at the earliest possible moment the building program outlined before the war and it is hoped that actual work will be begun in the spring of 1920 and that the new hospital buildings will be completed by the end of the following year. The expenses of the hospital for the year were $652,835, which were covered by receipts of a similar amount, $213,388 of which was contributed by the federation for the support of Jewish philanthropies. Base Hospital No. 3 had a very active service abroad, having cared for as many as 2,800 patients at one time. It was announced that the experimental stage of the cardiac clinic had been passed and it had been regularly incorporated as a part of the dispensary, and has been installed in quarters especially designed for it in the children's clinic.

PENNSYLVANIA

New Hospital.—A modern two story brick structure to cost more than $60,000 is to replace the Williamsport Private Hospital, destroyed by fire more than a year ago. An option on the adjoining residence has been secured, and the building will be used as a home for nurses.

Personal.—Dr. Howard L. Hull, Camp Hill, formerly associate chief medical inspector, has been appointed chief medical inspector of the state department of health, succeeding Dr. B. Franklin Royer, Harrisburg.——Dr. John L. Laird, Philadelphia, formerly chief of the genito-urinary dispensaries of the state board of health, has been appointed chief of the laboratory of the state board of health to succeed Dr. James B. Rucker, Jr., Philadelphia.——Dr. B. Franklin Royer, formerly assistant health commissioner of Pennsylvania, and after the death of Dr. Dixon, acting health commissioner of the state, was given the honorary degree of Doctor of Science by Ursinus College, February 20.

Philadelphia

Personal.—Dr. Alexander Sterling has been appointed assistant physician pro tem. in the department of medicine in the service of Dr. S. Solis Cohen, at the Jewish Hospital.—— Dr. S. Leon Gans has been appointed chief of the genitourinary dispensares of the state to succeed Dr. John L. Laird, resigned.——Dr. S. McClintock Hamill will be one of the three delegates from this country to the international conference on public health and child welfare at Cannes, France, the first week in April. The invitation was extended by Dr. Livingston Farrand, Boulder, of the American Red Cross.—— Dr. Dorothy Child has been appointed chief of the division of child welfare in the state department of health, succeeding Dr. Hamill, resigned. Dr. Child recently returned from France, where she was engaged in Red Cross work.——Drs. George F. Souwers, Charlotte S. Farrington, Frederick Van Gunten, Benjamin Brown and Walter M. Miller have been named assistant medical inspectors by the director of public health and charities.

WEST VIRGINIA

Public Health Council.—The West Virginia Public Health Council, presided over by Dr. Vincent T. Churchman, Charleston, announces that it will hold its next examination for licensure, July 15 to 17, at the Hotel Huntington.

Health Officers' Conference.—The next conference of health officers of West Virginia will be held at the Hotel Chancellor, Parkersburg, April 23, under the chairmanship of Dr. Samuel L. Jepson, state health commissioner and secretary of the state public health council.

CANADA

New Medical Bill Not Considered.—As no mention of the new medical bill was made in the lieutenant-governor's address before the Ontario legislature, it is feared it will not be dealt with this season, and if introduced at all, will most probably be withdrawn.

New Military Hospital Opened.—The new orthopedic headquarters for Canada Military Hospital was formally opened in Toronto, March 1. Lieut.-Col. Charles S. McVicar is the officer commanding. The institution has a capacity of 1,000 patients; eventually the orthopedic hospital at Davisville, North Toronto, will be evacuated, and the remaining patients sent down to the Christie Street Hospital.

Ontario Medical Association.—The thirty-ninth annual meeting of the Ontario Medical Association will be held in Toronto, May 28 to 30, under the presidency of Dr. G. Stewart Cameron, Peterboro. The following are the chairmen of sections: Dr. Edmund E. King, surgery; Dr. John Sheahan, St. Catharines, medicine; Dr. Benjamin P. Watson, obstetrics and gynecology, and Dr. Frank C. Trebilcock, Toronto, ophthalmology, otology, rhinology and laryngology.

Banquet to New Dean.—February 5, a banquet was given at the Ritz-Carlton, Montreal, in honor of Dr. Louis de Lotbinière Harwood, the new dean of the Faculty of Medicine of Laval University, Montreal. About 200 were present, of whom 150 were medical men, and Dr. Rodolphe Boulet, Montreal, president of the College of Physicians and Surgeons of the Province of Quebec, presided. The toast to the guest of honor was proposed by Prof. A. Achille Foucher.

Personal.—Dr. Antoin H. Desloges, Montreal, has been nominated as general medical superintendent of the hospitals for the insane of the Province of Quebec.——Capt. Rene E. A. Weston, Tillsonburg, Ont., who was with the Second Canadian Field Ambulance in France, was signally mentioned in the last dispatches of Marshal Haig.——Major Brefney R. O'Reilly, Toronto, chief medical officer in Canada of the Royal Air Force, has sailed for England.——Dr. Edward A. Lebel, Lieutenant-Colonel in the C. A. M. C., Quebec, who commanded the Canadian hospital at St. Cloud, France, was stricken with paralysis in the latter part of January.——Lieut.-Col. Percy G. Brown, M.B., Toronto, is now an officer of the Order of the British Empire.——Major John F. Burgess, M.B., Owen Sound, Ont., has become a member of the Order of the British Empire. He was wounded in October.——Dr. William H. Jeffs, Toronto, has received word that his son, Dr. Howard B. Jeffs, has been made chief medical officer in charge of the disembarkation of Canadian troops at Portland, Maine.——Dr. Charles E. Treble has been appointed roentgenologist to the Wellesley Hospital, Toronto.——Major C. Edward Cooper Cole, Toronto, has been appointed to the command of the military hospital at Witley, England.——Cols. Herbert A. Bruce and James A. Roberts, Toronto, have arrived home from overseas.

GENERAL

Influenza Squad Commended.—The Secretary of the Navy announced, March 4, that he had officially commended fifty-two enlisted men of the Navy who, during the recent influenza pandemic, voluntarily submitted to experiments at the Naval Hospital, Chelsea, Mass., to aid the surgeons to attempt to secure the cause and method of transmission of the disease and to secure a preventive.

Rockefeller Money for Medical Education.—At a meeting of the General Education Board of the Rockefeller Foundation, appropriations aggregating $1,108,525 were made to various educational institutions throughout the United States. Of this sum the largest amounts were given for medical education, $400,000 being given to Johns Hopkins University Medical School for the endowment of a department of obstetrics, and $150,000 to the Meharry Medical College at Nashville, Tenn.

Warning.—A warning has been issued by some of the medical book publishers regarding M. J. Maddox formerly of Boise, Idaho, who is soliciting orders for books from hospitals, sanatoriums and nurses. Maddox makes it a practice to collect money in advance, and then disappears without giving his customers anything for their money except a pleasant smile. Our readers should be on the lookout for this man and should beware of paying money to any agent with whom they are not personally acquainted.

Posture League Meeting.—The American Posture League held its annual meeting, March 8. After luncheon an address was made on posture in industry, by Mr. Harry Arthur Hoff, consulting engineer, after which clinical demonstration of methods of recognizing and recording posture were given by Dr. Stella S. Bradford of the Adams' Place, Pompton Lakes, N. J., and Miss Jessie H. Bancroft. Moving pictures and other lantern slides on posture were shown and addresses made on the anatomic demonstration of some of the articles resulting from the technical committees of the league, including the chairs.

Dinner for Dr. Purnell.—A dinner in honor of Dr. Caroline M. Purnell, Philadelphia, was given, Saturday evening, March 8, at the Hotel McAlpin, New York, by the American Women's Hospitals, whose commissioner in France she has been for the past five months. The American Women's Hospitals, besides its own hospitals at Luzancy, Seine-et-Marne and La Ferte-Milon, Arrondissement de Chateau-Thierry, Aisne, France, staffed entirely by physicians and dentists from its own membership, has had almost 100 of its members working under the American Red Cross in France, Italy, Serbia and Palestine, and is now supplying physicians for the American Committee for Relief in the near East. Six of their members have recently sailed to take charge of hospitals in Turkey and Asia Minor.

Organization of Red Cross for Peace.—At the February 15 meeting of the American Red Cross in Washington, reorganization was effected for carrying on the work of the organization on a peace basis. The War Council of the Red Cross retired, March 1, and its functions have been transferred to the Central Committee, though four of the members of the War Council remain as members of the executive committee. They are Henry P. Davison, New York; Eliot Wadsworth, Boston; Cornelius N. Bliss, Jr., New York, and George E. Scott, Chicago. Dr. Livingston Farrand, Boulder, formerly president of the University of Colorado, has succeeded ex-President Taft as chairman of the Central Committee. National officers were elected as follows: president, Woodrow Wilson; vice presidents, William H. Taft and Robert W. DeForest; treasurer, John Skelton Williams; counselor, Alexander King, and secretary, Stockton Axson.

Delegation to Rehabilitation Conference Arrives.—A delegation of prominent surgeons and educators from France, Belgium and Italy arrived in New York, March 6, to attend the international conference to be held from March 18 to 22 under the auspices of the Red Cross Institute for Crippled and Disabled Men. The delegates from the Belgian government are: Prof. Louis Alleman of the government institution for cripples at Port Villez, France, and Prof. Edmund Bronsart, director of the school of reeducation for French crippled soldiers at Montpelier, France. The delegates of the French government are: Dr. Morris Bourrilon, president of the Permanent Interallied Committee on War Cripples and director of the French National Institute for Crippled Soldiers, and Dr. Andre Treves. Professor Vittorio will represent Italy. The delegation coming from Canada will be led by Sir James Lougheed, and that from Great Britain will be headed by Major Robert Mitchell.

The Hospital Bill.—The conference report on House Bill 13026, providing hospital facilities for sick and disabled soldiers, sailors and others, has been agreed to in Congress and is now a law. Under it the Secretary of the Treasury (through the United States Public Health Service) is authorized to provide immediate additional hospital and sanatorium facilities for the care and treatment of discharged sick and disabled soldiers, sailors and marines, Army and Navy nurses (male and female), patients of the War Risk Insurance Bureau, merchant marine seamen, seamen on boats of the Mississippi River Commission, officers and enlisted men of the United States Coast Guard, officers and employees of the Public Health Service, certain keepers and assistant keepers of the United States Lighthouse Service, seamen of the Engineer Corps of the United States Army, officers and enlisted men of the United States Coast and Geodetic Survey, civilian employees entitled to treatment under the United States employees' compensation act, and employees on Army transports not officers or enlisted men of the Army now entitled by law to treatment by the Public Health Service. Under this law, the following properties are turned over for the purposes named: hospitals and sanatoriums at Camp Cody, N. M., Camp Hancock, Ga., Camp Joseph E. Johnston, Fla., Camp Beauregard, La., Camp Logan, Texas, and Camp Fremont, Calif.; the nitrate plant, Perryville, Md., and such other hospitals and dispensaries hereafter vacated by the War Department as may be required and found suitable for the needs of the Public Health Service. Among the other hospitals and sanatoriums mentioned are the Battle Mountain Sanatorium at Hot Springs, S. D., General Hospital 15 at Corpus Christi, Texas, the "Speedway" hospital at Chicago, a site for a sanatorium at Dawson Springs, Ky. (to be built), a hospital to be built at Norfolk, Va., one at Washington,

D. C., and others. The Secretary of War is authorized to turn over to the Public Health Service under this act hospital equipment and supplies, motor trucks and cars, etc., for the use of the hospitals and sanatoriums. For the purpose of carrying out the provisions of the act, the sum of about $9,000,000 is appropriated.

FOREIGN

Hookworm in Jamaica.—Dr. Powell Gardner of the Rockefeller Institute, New York, has arrived at Kingston, Jamaica, to engage in a campaign against hookworm disease begun by the local government.

The Kitasato Institute for Infectious Diseases.—The seventh graduation exercises of the Kitasato Institute at Tokyo, Japan, were held recently, thirty-nine graduates being given diplomas by the minister of the interior.

Ambulance Aeroplane Tested.—A 1,000 horse power aeroplane was tested in Paris, March 3, to determine its applicability as an ambulance. During the test, surgeons, hospital equipment and wounded were conveyed.

More Food for Poles.—The American Red Cross, March 6, dispatched from Switzerland a third special train of twenty-one cars loaded with provisions for the Polish people. The train was accompanied by a Swiss military escort.

The Ace Among the Army Surgeons of Italy.—The *Policlinico* states that Dr. C. Rizzo now has the record for military decorations, nine having been conferred on him, including five for deeds requiring exceptional courage.

Health Pad Calendar.—The Italian Red Cross has issued a pad calendar with maxims for individual and communal hygiene on each of the leaves, to be torn off day by day. This *Calendario della Salute* is sold for $1. The Rome headquarters are at the Libreria Mantagazza, via Nazionale 145.

Red Cross on Way to Poland.—The first contingent of the American Red Cross Commission to Poland, left Paris for Warsaw, February 21 and arrived in Warsaw, March 6. It was joined by another group at Berne. The commission is under the command of Walter C. Bailey, Lieut.-Col., M. C., U. S. Army, Boston, and consists of fifty members from all parts of the United States.

Endowed Chairs at the University of Glasgow.—It is reported that the University of Glasgow has received from Mr. William Guthrie Gardiner and Mr. F. C. Gardiner an endowment for three chairs in the university, these being the chairs of bacteriology, organic chemistry and physiologic chemistry. The endowment amounts to £20,000, or $100,000, for each chair, making a total of £60,000, or $300,000.

Red Cross Hospitals in Serbia.—The American Red Cross has already established a hospital at Uskub, under charge of Dr. Daniel J. McCarthy, Davenport, Iowa, and at Monastir under the charge of Dr. Regina F. Keyes, Buffalo. Other hospitals will be established in northern Serbia as they may be required. There are also physicians and dentists of the Red Cross at Nish, Belgrade and other points. In the Monastir district there is a special Red Cross commission to train Serbian peasants in American farming and methods, and to demonstrate to them the benefit of American agricultural machinery.

Influenza in Japan.—According to articles in the *Japan Medical World* there was an epidemic of influenza in various parts of Japan during the spring of 1918, although this fact was not published at the time. In October it assumed a pandemic character, and Kanai remarks that it may not be much exaggerated to say that nearly the entire populace was infected. The total number of cases among the soldiers was 25,915, of which 121 terminated fatally. Among the troops in Formosa, China and elsewhere, there were 4,218 cases with only nine deaths. The bacteriologic findings seem to be about the same as those reported elsewhere.

Deaths in the Profession Abroad.—**Dr. L. M. Bossi**, professor of obstetrics at the University of Milan, was assassinated there, January 31, by an oriental. He is known for his instrumental metal dilator for the uterus, and his contention that gynecologic disease is the basis for certain cases of mental impairment.——**Dr. R. Massalongo**, lecturer on medical pathology and neuropathology at the universities of Turin and Padua, chief of the public hospital at Verona, and author of numerous works on familial nervous diseases, on pituitary dystrophy, epilepsy and brain diseases in children, member of various medical societies in Italy and elsewhere and on the board of the Italian Internal Medicine Society.——**Dr. C. W. Sebardt** of Stockholm, who has always taken a leading part in the organization of pharmacists in Sweden and in raising the standard of pharmacies, public health and public welfare in general, aged 77. He was a member of the Swedish Medical Association for fifty-five years and was the delegate from Sweden to various international congresses of pharmacy.

BUENOS AIRES LETTER

Buenos Aires, Jan. 27, 1919.

Epidemic of Influenza

When the recent epidemic began to die away even in the more remote parts of the country, the people were alarmed by the appearance of a new focus at the port. The steamer *Demerara* brought some sick people from Santos, and their arrival spread the sickness again on the ship and at the Hotel de Immigrantes. Measures were taken to isolate the cases and the illness was checked. The severe epidemic which broke out in Paraguay and which extended to Misiones had completely declined by the first fortnight in January.

Bubonic Plague in Salta and Jujuy

The distant province of Jujuy situated in the extreme north of the country has been again attacked by the plague. When these small foci were observed, they were quickly isolated, but shortly afterward others appeared among the small towns of the neighboring province of Salta, especially in Rosario de Lerma, Carmen and Chicuana. According to the latest news cases have been observed at the gates of the city of Salta.

The Departamento Nacional de Higiene has sent a medical commission to Jujuy, directed by Dr. de la Sota, who has already returned. At this date another commission directed by Dr. Vaca has been sent to the province of Salta.

Diagnosis of Syphilis from Semen

In a preliminary note, Drs. Widakovich and Sires announce that in the semen of syphilitics they have encountered a high percentage of abnormal spermatozoa, two heads, two tails, etc. These abnormalities might serve in the diagnosis of the disease.

Specific Leukocyte Substances

In a recent work Dr. A. Bachmann affirmed that the leukocytes of immunized animals acquire immunizing properties, and that extracts of them possess a curative power superior to extracts of normal leukocytes.

The "Semana Medica"

The weekly review, the *Semana Medica,* celebrated January 18, with a festival gathering, the twenty-fifth anniversary of its foundation.

Injury of Hospital Medical Staff in Recent Uprising

In inaugurating a general strike recently, certain anarchistic elements sought to impart a revolutionary aspect to it, but in general their propositions met with no echo. However, it proved necessary for the police and the army to repress the isolated foci of rebellion. The public hospitals of the capital had to do an enormous amount of work, and some of the staff were barbarously shot at by the revolutionists. While lending his services, one intern of the hospital Ramos Mejia was hit in the right lung by a bullet. This occurred at the very doors of the hospital.

Personal

The professor of physiology, Dr. H. G. Piñero has had a cerebral attack, and on this account has asked to be relieved of his charge.

MEXICO LETTER

Mexico City, Feb. 23, 1919.

Official Regulation of Private Laboratories

The Departamento de Salubridad has issued orders to the effect that the private laboratories which make a practice of the Wassermann test must comply with certain requirements: They must be in charge of a duly registered physician or veterinarian who has obtained by written application a permit from the public health authorities to open the laboratory. The head of the laboratory must present a certificate signed by two honorable and known persons who guarantee the good faith and special skill of the applicant. If there are assistants in the laboratory, each must be certified in the same manner. The Wassermann test must be done not only with the classic procedure but also by the control technic of Hecht and Jacobsthal, and if necessary, the reaction shall be determined not only with the blood serum but with the cerebrospinal fluid. The laboratory shall be equipped with all the apparatus and materials required for this class of studies, a list of the same to be sent to the headquarters of the Departamento. This vigilance on the part of the public authorities will be felt quite severely in the private laboratories.

Regulation of Pharmacies

The discovery of the fact that in certain pharmacies the druggists were substituting for the drugs prescribed by the physician others that were less expensive, has called the attention of the Departamento de Sanidad to the necessity for supervision of pharmacies. The drug store which was discovered *in flagrante delictu* has been closed and vigilant supervision has been extended to the others. A plan is now being discussed for official regulation of pharmacies which will provide for drastic measures against fraud, and will effectively guarantee the sacred interests of the public.

Mexico City, March 3, 1919.

Official Inspection of Public Health Service

The president of the Departamento de Salubridad has left for an inspection trip, intending to visit the sanitary bureaus established in the towns along the border and the sea coast towns, to ascertain by personal inspection how these stations are functioning and to correct the deficiencies noted. During his absence, the secretary of the Departamento will assume his work.

Inmates of Hospital Rebel

Not long ago the inmates of the hospital "Morelos," an institution devoted exclusively to the care of prostitutes with venereal diseases, rebelled and assaulted the police guarding the establishment and tried to escape. It was necessary to resort to forcible measures to restrain them, and several police were wounded. This is the third occasion, within a few months, in which events of this kind have occurred. The matter should be investigated to see if the complaints of the patients are justified and whether the cause might be remedied.

Beggars in Mexico

In order to reduce the large numbers of beggars with which the city is swarming, the authorities have set apart one pavilion in the old Belem prison to adapt it for an asylum for beggars where those incapable of self support will be given food and shelter. The children who have no one responsible for them will be sent to industrial schools, the sick to the hospitals, and those who are simply lazy will be compelled to work. This will leave in the Belem asylum only those who are absolutely incapable of self support from their advanced age or other circumstances.

Law to Combat Vagrancy

Among the numerous bills for proposed legislation which the department for industry, commerce and labor is now studying, is one important bill dealing with a question which has been much discussed but has never been settled in this country. The outline of the bill, which will probably be presented for the consideration of congress during its next session, deals with the disfranchisement of habitual vagrants and prostitutes, depriving them of political rights. According to the proposed bill, this will exclude from voting the habitual drunkards, gamblers, and white slavers and those who have been convicted of crimes against common law.

The Consumption of Food

A local paper, the *Excelsior,* has been publishing an estimate of the food consumed by the inhabitants of this city, investigating the amount of foodstuffs imported and dividing the figures by the estimated population, namely, 800,000. According to this calculation, each person living in the City of Mexico consumes daily 90 gm. of meat, 95 gm. of bread, 357 gm. of maize, 65 of frijol, 11 of potato, 6 of rice, 232 of sugar, and 6 of milk. These figures are only approximative, as a large portion of the flour and sugar are used in the manufacture of pastry and candy which are sold outside of the city. The exact number of the inhabitants is not known at present, the last census having been taken in 1910.

Reciprocity Between Mexico and Spain

The statement quoted recently in The Journal from a Mexican exchange to the effect that the reciprocity treaty between Mexico and Japan is the only reciprocity treaty into which this country has entered is incorrect. Mexico concluded a similar arrangement with the Spanish government some ten years ago.

LONDON LETTER

London, Feb. 19, 1919.

Another Epidemic of Influenza

Influenza has broken out again, making a third wave in less than a year. Generally speaking, the disease retains its now classic form, but there are a few minor points of difference. Attacks tend to begin rather less suddenly and less violently, and the local manifestations in the throat and air sinuses have been fewer. The cases that are complicated by pneumonia tend to follow the usual course of local consolidation, crisis, and slow clearing of the chest, common in the years before the war. This is in contrast with the rapidly fatal septic type with acute toxemia characterizing the summer and autumn epidemics, and suggests a distinct decrease in virulence. Of those attacked previously very few have been again infected. Some immunity seems to have been established, for in most cases of reinfection there are only vague rheumatic pains and malaise lasting a few days.

The Influenza Epidemic in South Africa

In the House of Assembly at Cape Town, Sir Thomas Watt, acting prime minister, gave some interesting statistics of the recent influenza epidemic. In two months the epidemic carried off 11,736 Europeans and 127,700 of the natives and colored population. As in England, the epidemic attacked not the old or the weak but the middle-aged and the strong.

An Ununitable Profession

It is an old complaint that the medical profession is ununited on medicopolitical questions, that it is composed of divergent factions, to say nothing of a large body that will join no association of any kind and take no part in politics. That it is ununitable seems to be shown by the failure of a recent attempt at union. The intention of the government to introduce a ministry of health, which is considered to involve important changes in the relations of the profession to the public, has aroused a good deal of apprehension. This was evidently the cause of a mass meeting of the profession under the chairmanship of Prof. William Russell of Edinburgh being called in London by a circular postcard. The postcard stated that these two resolutions would be proposed: 1. "In view of prospective legislation and the proposed establishment of a ministry of health, and having regard to the experience of the medical profession at the time of the passing of the national insurance acts, the time has arrived when a body representative of the whole profession should be established, to watch the interests and be prepared to act in an advisory capacity as occasion demands," and 2. "That a provisional committee be now formed with the object of securing the election of such a body." About 500 physicians attended. Though the fact was not announced, the meeting had evidently been organized by the National Medical Union, a body composed of nonpanel physicians whose object is "to maintain the freedom of the medical profession in its professional and personal relations with the public and to support the public in maintaining a corresponding freedom." The first resolution, given above, was moved by a member of the union, who pointed out that in these days of democratic and socialistic tendencies it would be suicidal for the medical profession to stand aloof when legislation affecting it was proposed. At present there was no body representative of the profession as a whole. He considered that the British Medical Association had lost the confidence of the profession since the great debacle of 1913. He was alluding to the fact that the majority of its members refused to follow the lead of the representative body which condemned the insurance act as derogatory to the profession and asked the profession not to work it. The resolution was opposed by representatives of the British Medical Association, which protested that it was quite capable of doing what was proposed. Let those who thought they could do better join it, and capture the machine and make it work in their way. To found a new body would only further divide the profession. The first resolution was carried by a majority of 182 against 83. To the second resolution an amendment was proposed: "That in view of the urgency arising from contemplated legislation, the 'Parliamentary Medical Committee' be appointed as the provisional committee for drawing up the constitution of a body to develop along the lines indicated by the first resolution." The formation of the "Parliamentary Medical Committee" for the purpose of promoting medical representation in Parliament was announced in a previous letter to The Journal. It was another attempt to organize and work independently of the British Medical Association. The amendment was opposed on the ground that as a resolution for an entirely new development had been passed, it was inconsistent to extend the powers of an already existing committee. If the Parliamentary Medical Committee wanted larger authority, it ought to appeal to a meeting summoned for the purpose. The amendment was rejected by a majority of 105 against 87. Another amendment was then moved, that "no organization is capable of effectively representing the interests of the medical profession unless it is a registered trade union." This amendment was moved by a representative of the Medical Political Union (a body, as explained in a previous letter, consisting mainly of panel physicians and registered as a trade union). The mover referred, amidst great applause, to the success with which trade unions had made the government "bend the knee." On the amendment being put, the show of hands seemed strongly in favor of it, but the count declared it to be lost by 71 to 73. A recount was demanded from all parts of the hall, but was refused by the chairman, who then found it impossible, because of interruption, to continue the business of the meeting, which he declared closed.

Dr. Cox, secretary to the British Medical Association, in an interview published in the *Morning Post,* said that "the reason why the meeting was such a fiasco was that it was composed of three sections, who are only united in one thing, and that is dissatisfaction with the British Medical Association. First, there is the section which called the meeting, the National Medical Union, whose main object is to fight the national insurance act and all connected with it. Then there is the Medical Political Union, which believes that the only hope for the medical profession is trade unionism. The third body, the Medical and Parliamentary Committee, sprang out of a desire during the recent general election to promote the candidature of medical men for Parliament. The association has held aloof from all these things, because it considers it has the machinery for doing all the great mass of the profession wants in the way of organization, and it would be betraying its principles if it encouraged the setting up of sectional bodies for purposes which the association is quite capable and willing to carry out, with the exception of trade unionism, which the association does not believe in. It has proved on countless occasions that it is both able and willing to defend the interests of the profession. The answer the association would give to the people who were at that meeting, and who evidently did not know what they wanted, is that the proper field for their energies would be inside the association helping to reform it, if they think it needs reforming, rather than give the outside public the idea that the medical profession is a disorganized mob which does not know what it wants."

PARIS LETTER

Paris, Feb. 13, 1919.

Death of Professor Blanchard

Dr. Raphael Blanchard, professor of parasitology and medical natural history in the Paris faculty of medicine, has just died at the age of 62 years. The death of this noted savant is a distinct loss to French science. He was an authority in matters of human parasitology and was the representative of France at many international congresses. He was born Feb. 28, 1857, at Saint-Christophe (département d'Indre-et-Loire), the grand-nephew of the celebrated French aeronaut, Pierre Blanchard. He began his medical studies in Paris in 1874. In 1876 he became the assistant of Pouchet in the department of zoologic histology. Later, he worked under Paul Bert at the Sorbonne as assistant in physiology. In 1883 he was made a professor of the Paris medical faculty, and in 1897, on the death of Professor Baillon, he was called to the chair of medical natural history in the same faculty. At his request, this chair became the chair of parasitology and medical natural history in 1907. In 1894, he was made a member of the Académie de médecine in the section of therapeutics and medical natural history, and for seven years he has served as secretary. In 1902, Professor Blanchard founded the Institut de médecine coloniale, and was also instrumental in founding an organization to fight the spread of contagion by insects. For twenty years he was secretary general of the Société zoologique de France. In 1889, assisted by Professor A. Milne-Edwards, he organized the Congrès international de zoologie which, since then, has met triennially, and of which he was the permanent secretary general. Besides, he was one of the founders of the Société française d'histoire de la médecine, and was its first president. He founded the *Archives de Parasitologie,* which is published in several languages. He is the author of numerous articles on zoology, anatomy and comparative physiology, anthropology, and history of medicine, but his principal works were on the parasitic origin of disease. He was also the author of a "Traité de zoologie médicale," (1885-1888), and of a book on mosquitoes (1905). He had also begun a "Corpus inscriptionum," a collection of inscriptions and epitaphs, devoted to medicine and biology.

Tribute to French Surgeons

In an eloquent address delivered by Dr. Louis Mourier, under secretary of state for the Service Santé militaire, at the annual meeting of the Société de chirurgie de Paris, he dwelt on the splendid work done by French surgeons during the war, expressing the gratitude both of the army and of the nation. Between March 1 and Nov. 11, 1918, more than one million wounded, sick and gassed persons had been brought in by the Service de Santé and distributed in hospitals. More than one half of this number were able to return to their army detail after several weeks, clinically cured.

Medical Service in the Liberated Regions

At the last meeting of the Association générale des médecins de France, Dr. Thierry, deputy from the *département de la Meuse,* stated that the minister of the liberated regions had decreed that each doctor who will return to his home in the liberated regions will receive a monthly compensation of 500 francs for the succeeding two years. Furthermore, he will be furnished with a vehicle: automobile, side-car, etc. The undersecretary of state of the Service de Santé militaire has ordered that the needed instruments be lent to these doctors.

Trephining in a Front Line Serbian Hospital

At a recent meeting of the Société de chirurgie de Paris, Dr. Petrowitch reported statistics in trephining made in a front line Serbian army hospital. Of 152 cases of head wounds received at this hospital, 69 per cent. terminated fatally, more or less rapidly, without having been operated on. In the other cases trephining was done and proved successful in 76 per cent. The patients who did not present an open cerebral lesion, that is to say, without a lesion of the dura mater, all recovered (15 cases). The cases in which there existed wounds of the dura mater and of the brain, gave 63 per cent. of cures (15 recoveries and 9 deaths). These statistics confirm the results obtained on the field of battle by French surgeons.

Children's Welfare Bureau of the American Red Cross

Dr. B. Weill-Hallé of Paris recently reported to the Société de pédiatrie on the activities of the Bureau de l'Enfance of the American Red Cross. The first contingent, under the direction of Dr. W. B. Lucas of the University of California, arrived in France, Aug. 12, 1917. The personnel of this child welfare bureau numbered 450, including doctors, nurses, hygienists, secretaries, lecturers, etc. Its aim was to give immediate aid to the children of the refugees, repatriates, etc., and to seek to offset the loss from the low birth rate of France. The first part of this work was done at Meurthe-et-Moselle, Nelles, Amiens, and Evian, where 65,000 examinations of children were made, at Lyons, etc. To carry out the second part of its program, the bureau carried on an energetic propaganda from three different sides: propaganda by the doctors in the dispensaries and the *consultations de nourrissons;* propaganda by the visiting nurses, and by means of general publicity, making use of tracts, brochures, posters and placards, picture post cards, cinematograph films, addresses and exhibits. As a result of the activities of the devoted corps of nurses under the direction of Miss Ashe, a school for visiting nurses for children has been organized at Lyons and at Paris. Dr. Weill-Hallé also reported on the work done by the Patronage franco-américain de la première enfance in one of the wards of Paris, the XLV-e arrondissement. This organization has taken charge of all the births in this ward, visiting the homes of all the mothers.

Donation of Argentine Physicians to French Medical Relief Fund

The doctors of the Argentine republic have manifested their regard for France by constituting a Comité de secours for their French confrères who have become victims of the war. A subscription fund has been started and 41,500 francs have been turned over to the *Caisse de secours de guerre,* the war relief fund, of the Association générale des médecins de France.

Deaths

Richard Andrews Reeve, Toronto, Ont.; Queens University, Kingston, Ont., 1865; University of Toronto, 1889; aged 76; a specialist on diseases of the eye and ear; lecturer on diseases of the eye and ear in the *Toronto School of Medicine* from 1872 to 1887, and since 1887 professor of ophthalmology and otology in the University of Toronto; dean of the Faculty of Medicine from 1906 to 1908; for twelve terms president of the Alumni Association of the University; founder of the Reeve Scholarship; a member of the council and senate of the University of Toronto, and of the board of regents of Victoria University, Coburg, Ont.; member of many scientific societies; past president of the British Medical Association, of the Canadian Medical Association and of the Toronto Academy of Medicine; who had conferred on him the honorary degree of LL.D. by the University of Toronto, in 1902 and by McGill University, Montreal, and the University of Birmingham, England, in 1911; one of the most striking personalities in the medical profession of the dominion; an operator of high rank; died suddenly on the street in Toronto, January 27.

Thomas Addis Emmet, New York City; Jefferson Medical College, 1850; aged 91; a member of the Medical Society of the State of New York; who was appointed visiting physician to the Emigrant Refuge Hospital, Ward's Island, in 1851; assistant surgeon to the Woman's Hospital in the State of New York in 1855; surgeon in chief of the institution from 1861 to 1872, and since that time visiting surgeon or consulting physician or surgeon to many public hospitals in New York City; an eminent gynecologist who introduced many new operations and methods of treatment; author of a textbook which has been standard for many years on "Principles and Practice of Gynecology"; a world figure in the fight for Irish home rule; who had conferred on him by the pope the title of Knight Commander of St. Gregory the Great in 1906, and the Laetere Medal by Notre Dame University, South Bend, Ind., as an award to the Roman Catholic whose work had been of the greatest benefit to humanity; died at his home, March 1.

John Waite Mitchell ⊕ Providence, R. I.; Bellevue Hospital Medical College, 1871; aged 70; visiting physician to the Rhode Island Hospital, Providence, from 1875 to 1883; president of the Rhode Island State Medical Society from 1889 to 1891; and of the Rhode Island Emergency and Hygiene Association and president of the Providence Medical Society from 1886 to 1889; trustee and consulting physician to the Providence Lying-In Hospital; and consulting physician to St. Elizabeth's Home and the Rhode Island Catholic Hospital, Providence; died at his home, February 27, from pneumonia.

William Hughes Wells, Philadelphia; Jefferson Medical College, 1891; aged 59; a member of the Medical Society of the State of Pennsylvania; assistant professor of obstetrics in his alma mater since 1913; assistant obstetrician to Jefferson Medical College Hospital; physician to Willing's Day Nursery, Philadelphia; a fellow of the College of Physicians of Philadelphia; author of several works on gynecology and obstetrics; died in the Jefferson Hospital, February 26.

Alfred Whitehead, Baltimore; Baltimore University, 1890; M.R.C.S., Queens College, Birmingham, England, 1871; aged 70; ship surgeon of the Peninsular and Oriental Steamship Company from 1872 to 1878; professor of diseases of children in the Baltimore School of Medicine from 1884 to 1889; and professor of anatomy and clinical surgery from 1889 to 1894; died at his home, February 27, from heart disease.

James L. McLean, Greenwood, Miss.; University of Louisville, Ky., 1875; aged 64; at one time a member and first vice president of the Mississippi State Medical Association; formerly professor of clinical gynecology in the College of Physicians and Surgeons, Memphis, Tenn.; local surgeon of the Illinois Central and Southern railways; died at his home, about February 21, from cerebral hemorrhage.

George E. Schuyleman, Portland, Ore.; Lincoln (Neb.) Medical College, Eclectic, 1904; aged 43; formerly of Glenville, Neb.; who had assumed the practice of a physician at Natko, Kan., during the recent influenza epidemic, and suffered a breakdown, was found hanging from the wheel of an irrigation headgate near Scott's Bluff, Neb., February 24.

Leo Louis Cahill, Springer, N. M.; University of Illinois, Chicago, 1898; aged 47; at one time a member of the New Mexico Medical Society; local surgeon of the Santa Fe System for several years; who broke down from overwork during the influenza epidemic, and was removed first to Raton, N. M., and later to the Woodcroft Hospital, Pueblo, Colo.; died in that institution, January 26.

William Shackelford, The Dalles, Ore.; Jefferson Medical College, 1861; aged 80; a pioneer practitioner of Oregon and Washington; surgeon of the *94th New York Volunteer* Infantry during the Civil War, and later surgeon, U. S. Army, until 1870; for several terms a member of the city council of The Dalles, and until recently health officer of the city; died at his home, February 21.

John Chandler Wysor ⊕ Clifton Forge, Va.; College of Physician and Surgeons, Baltimore, 1878; aged 64; a member of the Southern Surgical and Gynecological Association; for many years chief surgeon of the Cresapeake and Ohio Railway Hospital, Clifton Forge, and thereafter consulting surgeon; died at his home, February 23, from pneumonia.

John C. Pickett, Nelsonville, Ohio; College of Physicians and Surgeons, Baltimore, 1896; aged 51; a member of the Ohio State Medical Association; died at his home, February 25, from the effects of a gunshot wound of the head, self-inflicted, it is believed, with suicidal intent, while despondent on account of ill health.

William Benjamin Jones ⊕ **Lieut., M. C., U. S. Army,** Rochester, N. Y.; College of Physicians and Surgeons, 1884; aged 57; consulting surgeon to the Willard State Hospital, and the Craig Colony for Epileptics; surgeon to St. Mary's Hospital, Rochester; died suddenly in his automobile, March 1.

Timothy Matlack Cheesman ⊕ Garrison-on-Hudson, N. Y.; College of Physicians and Surgeons of the City of New York, 1878; aged 66; a fellow of the New York Academy of Medicine, and a member of the American Bacteriological Society; died at his home, February 25, from cerebral hemorrhage.

Frederick Mathews, New York City; College of Physicians and Surgeons in the City of New York, 1883; aged 58; a member of the Medical Society of the State of New York; visiting surgeon to the German Polyclinic Hospital, and to the Stuyvesant Polyclinic; died at his home, February 28.

Clarence Edward Farish ⊕ **Lieut., M. C., U. S. Army,** Mobile, Ala.; University of Alabama, Mobile, 1906; aged 36; while driving his automobile over a grade crossing at Brewton, Ala., February 20, was struck by a train and died from his injuries while being taken to a hospital in Mobile.

Hyman Caro ⊕ **Capt., M. C., U. S. Army,** Chelsea, Mass.; Harvard Medical School, 1914; aged 29; formerly a member of staff of the Monson State Hospital, Palmer, Mass.; on duty with the American Expeditionary Forces; died in Mars, France, January 22, from bronchial pneumonia.

Hugh David Ward ⊕ **Asst. Surg., U. S. P. H. S.,** Southport, N. C.; University of Pennsylvania, Philadelphia, 1914; aged 33; on duty in the extracantonment zone around Camp Wadsworth, Columbia, S. C.; died in Spartanburg, S. C., February 18, from pneumonia following influenza.

George Riley Cate, Brookline, Mass.; Bowdoin Medical School, Brunswick and Portland, Me., 1894; aged 51; medical director of the Fisk Hospital, Brighton, Boston; who was struck by a trolley car, February 21; died from his injuries in Fisk Hospital a few hours later.

Julian W. Sloan ⊕ Richmond, Va.; Medical College of Virginia, Richmond, 1904; aged 40; assistant professor of clinical medicine in the University College of Medicine, Richmond, Va.; city physician for the west end district of Richmond; died at his home, February 26.

Thomas Benton Dickson, Ramona, Okla.; Memphis (Tenn.) Hospital Medical College, 1895; aged 50; a member of the Oklahoma State Medical Association; also an oil man; was robbed and beaten to death in his room in a hotel in Kansas City, February 22.

John Eberly Kuykendall ⊕ **Capt., M. C., U. S. Army,** Eugene, Ore.; Cooper Medical College, San Francisco, 1912; aged 33; in command of the 361st Ambulance Company, A. E. F.; died in LeMans, France, February 23, from meningitis.

Douglas Blair Mayes ⊕ Americus, Ga.; Vanderbilt University, Nashville, Tenn., 1906; aged 36; secretary of the Sumter County Medical Society from 1915 to 1917; city physician of Americus for several years; died at his home, February 14.

William Wirt Piper, Cleveland; Dartmouth Medical School, Hanover, N. H., 1867; aged 79; assistant surgeon of the Thirteenth United States Heavy Artillery during the Civil War; died at his home, February 24, from heart disease.

⊕ Indicates "Fellow" of the American Medical Association.

Frank B. Florentine ⊕ Saginaw, Mich.; Rush Medical College, 1876; aged 68; surgeon and gynecologist to St. Mary's Hospital and Saginaw General Hospital, and Women's Hospital, Saginaw, Mich.; died at his home, January 31, from diabetes.

George Aloysius Cunningham, Philadelphia; Jefferson Medical College, 1904; aged 39; formerly surgeon to the Western Pennsylvania Hospital, Pittsburgh; died in the University Hospital, Philadelphia, February 21, from pneumonia.

Charles D. Hildebrand, Loganville, Pa.; College of Physicians and Surgeons, Baltimore, 1881; aged 59; a member of the Medical Society of the State of Pennsylvania; died at his home, about February 25, from cerebral hemorrhage.

Britain W. Lockhart, Lula, Ga.; Medical College of Georgia, Augusta, 1883; aged 67; president of the Hall County Medical Society in 1914; also an ordained minister; died at his home, February 11, from pellagra.

Joseph T. Bryan, Louisville, Ky.; Pulte Medical College, Cincinnati, 1883; aged 59; professor of obstetrics and clinical pediatrics, in the Southwestern Homeopathic Medical College, Louisville; died at his home, February 23.

George W. Finch, Los Angeles; California Eclectic Medical College, Los Angeles, 1890; aged 64; professor of materia medica and therapeutics in his alma mater; died at a hospital in Los Angeles, about February 23.

James N. Porter, Boyes, Mont.; for many years a practitioner of Prairie City, Iowa; aged 76; a veteran of the Civil War; died at the home of his daughter in Boyes, February 10, from cirrhosis of the liver.

Abraham H. Lifchutz, Chicago; Barnes Medical College, St. Louis, 1899; aged 49; at one time a member of the Illinois State Medical Society; died at his home, February 28, from mediastinal tumor.

Nathan Ziegenfuss ⊕ South Bethlehem, Pa.; Jefferson Medical College, 1892; aged 69; formerly president of the South Bethlehem board of health; died at his home, about February 24.

Daniel Webster Roberts, St. Augustine, Fla.; Jenner Medical College, Chicago, 1896; aged 52; a colored practitioner; died at his home, about February 21, from pneumonia.

William Gray Adams, Boston; Harvard Medical School, 1897; aged 46; for eight years an instructor in Tufts College Medical School, Boston; died at his home, January 2.

Marriages

James Newton Alexander, Capt., M. C., U. S. Army, Roundup, Mont.; chief operating surgeon, Base Hospital No. 39, Base Section No. 7, La Rochelle, France, to Mlle. Germaine Kiere of Antwerp, Belgium, at La Rochelle, February 8.

Andrew Morton Carr, Jr., Lieut., M. C., U. S. Army, Chicago, on duty with the Presbyterian Hospital Unit, A. E. F., at Limoges, France, to Miss Ruth Carolyn Bennett of Springfield, Ill., at Limoges, recently.

Floyd Elwood Keene, Capt., M. C., U. S. Army, Philadelphia, on duty with the Pennsylvania Base Hospital No. 20, A. E. F., to Miss Martha Bussiere at Chatel-Cuyon, France, January 27.

John Howard Hall, Capt., M. C., U. S. Army, Atlanta, Ga., on duty at Rockwell Field, San Diego, Calif., to Miss Irene Jeanne Hawkins of Sacramento, February 10.

Frank Leech, Major, M. C., U. S. Army, Washington, D. C., on duty at Fort Sill, Okla., to Miss Myrtle Adele Tatum of Tatum, Va., February 9, at Greenville, S. C.

Herbert Alexander Bruce, Col., F. R. C. S., A. M. S., Toronto, Ont., to Miss Angela Hall, at St. Margaret's Church, Westminster, London, England, February 3.

Benjamin Harrison Adams, Asst. Surg., Lieut. (j. g.), U. S. N. R. F., Ocheyedan, Iowa, to Miss Marguerite Schaefer of Highland Park, Ill., recently.

Maurice Charles Pincoffs, Jr., Lieut., M. C., U. S. Army, Chicago, to Miss Katherine Brune Randall of Baltimore, at Catonsville, Md., March 1.

Hugh Miller Moore to Miss Elizabeth Beaton, both of Oxford, Ohio, February 19.

Morris Cassel to Miss Edith Kessler, both of Brooklyn, February 16.

The Propaganda for Reform

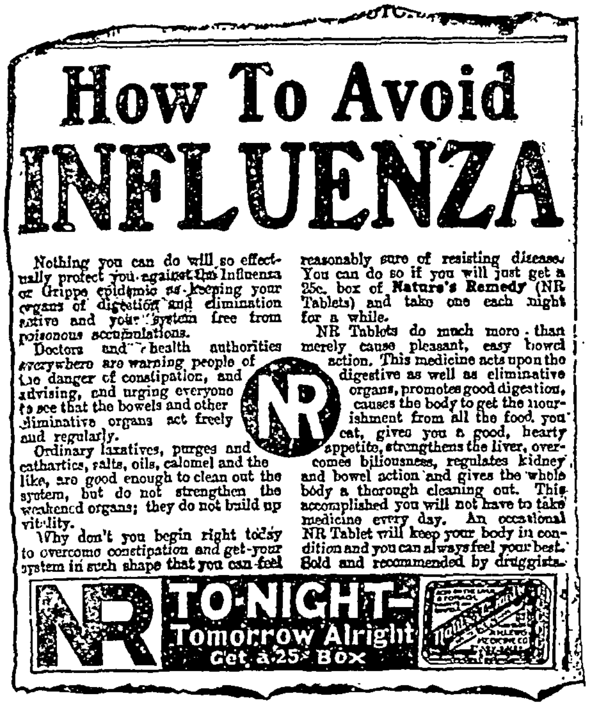
In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

NATURE'S REMEDY TABLETS

A. H. Clark, Ph.G., B.S.

From the Chemical Laboratory of the American Medical Association

"Nature's Remedy" is manufactured by A. H. Lewis Medicine Co., St. Louis. It is sold in 25 cent, 50 cent, and $1 packages. Three of the largest size packages were purchased on the open market and examined in the Association's Chemical Laboratory. Nature's Remedy comes in a tin box, containing an advertising circular, a guarantee blank, and 180 tablets. The advertising circular states that Nature's Remedy is a vegetable preparation and "acts on the stomach, liver, kidneys, and bowels," that it contains no digestives, but that its "purpose in dyspepsia, indigestion, bad breath, loss of appetite, sick headache, and rheumatism is to increase the elimination and keep the intestinal tract clean." The greater part of the circular is devoted to the exploitation of other nostrums of the A. H. Lewis Medicine Co.—"nerve pills," a liniment, headache tablets, and "Sans-Pareil" an "emmenagogue and uterine tonic." The list of diseases and indications for which these alleged remedies are recommended on this circular number about fifty.



How To Avoid
INFLUENZA

Nothing you can do will so effectually protect you against the Influenza or Grippe epidemic as keeping your organs of digestion and elimination active and your system free from poisonous accumulations.

Doctors and health authorities everywhere are warning people of the danger of constipation, and advising, and urging everyone to see that the bowels and other eliminative organs act freely and regularly.

Ordinary laxatives, purges and cathartics, salts, oils, calomel and the like, are good enough to clean out the system, but do not strengthen the weakened organs; they do not build up vitality.

Why don't you begin right today to overcome constipation and get your system in such shape that you can feel reasonably sure of resisting disease. You can do so if you will just get a 25c. box of **Nature's Remedy** (NR Tablets) and take one each night for a while.

NR Tablets do much more than merely cause pleasant, easy bowel action. This medicine acts upon the digestive as well as eliminative organs, promotes good digestion, causes the body to get the nourishment from all the food you eat, gives you a good, hearty appetite, strengthens the liver, overcomes biliousness, regulates kidney and bowel action and gives the whole body a thorough cleaning out. This accomplished you will not have to take medicine every day. An occasional NR Tablet will keep your body in condition and you can always feel your best. Sold and recommended by druggists.

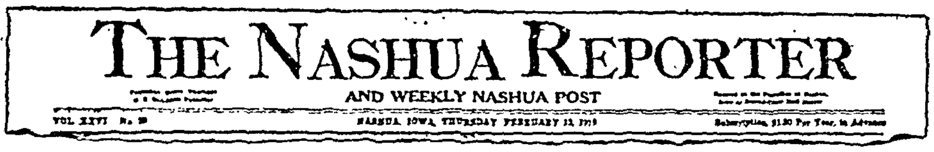
NR TO-NIGHT—
Tomorrow Alright
Get a 25c Box

Of course the epidemic of respiratory disease was capitalized.

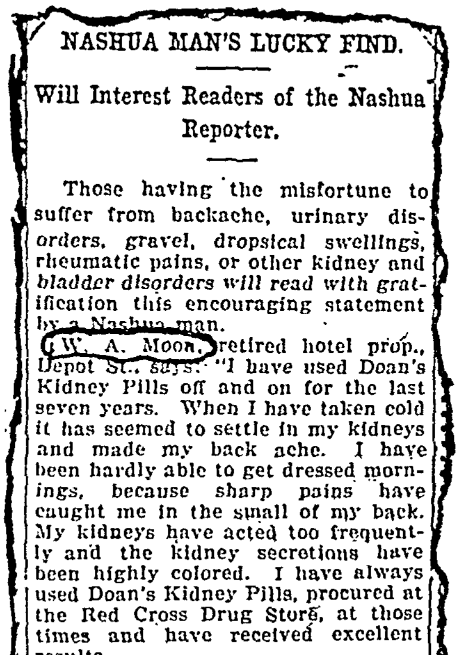
A booklet issued by the A. H. Lewis Medicine Co. gives a "formula"(?) for Nature's Remedy. It is stated that there are *ten* ingredients entering into its composition. The manufacturers generously name *seven* of these ingredients and admit that "were it not for the vast number of imitators who are ever ready to prey upon the business of established firms and the public we would gladly print the entire formula, for we are even more proud of the three unnamed than we are of the ones given."

The seven ingredients are Burdock, Juniper, Sarsaparilla, Mandrake, Rhubarb, Dandelion and Prickly Ash. There was so little about these to make one share the feeling of pride expressed by the exploiters that diligent search was made for the unnamed three on the chance that something worthy of mention might be found. Chemical analysis showed the presence of aloes, and traces of some alkaloidal drug. The tablets had the characteristic odor of aloes. Extracted with diluted alcohol, an extract representing 61.2 per cent of the tablet material was obtained. Extracted successively with ether, chloroform, and alcohol, a total of 63.6 per cent extractive was obtained. Extracted with water, an extractive representing 50 per cent was obtained. In every case the extractive resembled aloes in color, odor, and taste and gave the characteristic borax color reaction described in the U. S. Pharmacopoeia.

DOAN'S KIDNEY PILLS—TESTIMONY FROM THE TOMBS NO. 5



THE NASHUA REPORTER
AND WEEKLY NASHUA POST



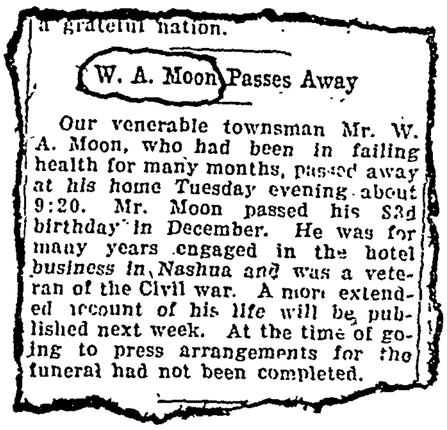
NASHUA MAN'S LUCKY FIND.

Will Interest Readers of the Nashua Reporter.

Those having the misfortune to suffer from backache, urinary disorders, gravel, dropsical swellings, rheumatic pains, or other kidney and bladder disorders will read with gratification this encouraging statement by a Nashua man.

W. A. Moon, retired hotel prop., Depot St., says: "I have used Doan's Kidney Pills off and on for the last seven years. When I have taken cold it has seemed to settle in my kidneys and made my back ache. I have been hardly able to get dressed mornings, because sharp pains have caught me in the small of my back. My kidneys have acted too frequently and the kidney secretions have been highly colored. I have always used Doan's Kidney Pills, procured at the Red Cross Drug Store, at those times and have received excellent results.

Mr. Moon is only one of many Nashua people who have gratefully endorsed Doan's Kidney Pills. If your back aches, if your kidneys bother you, don't simply ask for a kidney remedy, ask distinctly for DOAN'S KIDNEY PILLS, the same that Mr. Moon had, the remedy backed by home testimony. 60 cents at all stores. Foster-Milburn Co., Props. Buffalo, N. Y. "When your back is lame—remember the name."



a grateful nation.

W. A. Moon Passes Away

Our venerable townsman Mr. W. A. Moon, who had been in failing health for many months, passed away at his home Tuesday evening about 9:20. Mr. Moon passed his 83d birthday in December. He was for many years engaged in the hotel business in Nashua and was a veteran of the Civil war. A more extended account of his life will be published next week. At the time of going to press arrangements for the funeral had not been completed.

Two clippings from the *Nashua Reporter* of Feb. 13, 1919. The Doan's Kidney Pills advertisement opines that Nashua citizens "will read with gratification" the "encouraging statement" of Mr. W. A. Moon. *The encouragement will doubtless be tempered by the information given on another page of the same paper showing that Mr. Moon had been dead two days when his testimonial appeared.*

Since this examination accounted for but one of the mysterious *trio of* drugs, it was decided to make a microscopic examination, and the aid of E. N. Gathercoal, Instructor in Pharmacognosy in the University of Illinois School of Pharmacy, was sought. The microscopic examination confirmed the chemical findings as to aloes, and also established the presence of powdered cascara sagrada in abundance. Evidence of belladonna root in small quantities was also found and since the chemical examination showed traces of alkaloidal drug present it is possible that the third mysterious stranger is belladonna root. The microscopist's report further stated that rhubarb, as well as all the other seven named drugs, if present at all, are there in such small quantities that no evidence of their presence could be seen.

Let us analyze these analyses: *Aloin, the active constituent of aloes, has some of the characteristics of aloes but the dose is much less, namely, ¼ grain. A small proportion of aloin added to the tablets would greatly increase their activity. Further, one of the seven drugs mentioned as being in Nature's Remedy is mandrake, whose active constituent is the resin, podophyllin, one of the most powerful hydragogue cathartics known.*

As examination failed to show mandrake present, it was decided to give the tablets a physiologic test. One tablet, taken in the late afternoon according to directions, resulted in profuse watery stools early the following morning, the effect continuing through the day. As the amount of powdered cascara and aloes shown to be present in this tablet could not possibly have such violent hydragogue effect, it therefore seems evident that the mandrake is present as podophyllin, and that aloin is present with the aloes.

A little consideration of the dosage of the drugs mentioned in connection with Nature's Remedy shows clearly the absurdity of such a shotgun mixture, assuming that the drugs mentioned are really there. A table will better convey the idea. The doses given are taken *from the* U. S. P., N. F., *or* U. S. Dispensatory, and are average doses:

	Average dose of the drug in grains	Assuming the drugs present as extracts, the dose, in grains, would be about
Burdock	30	6
Juniper berries	60	12
Sarsaparilla ...	30	6
Mandrake	5	1 (podophyllin ⅙)
Rhubarb	15	5
Dandelion	150	30
Prickly ash ...	30	6
Aloes	4	2 *(aloin ¼)*
Cascara	15	3
Belladonna root	1	⅕
	340	71

A tablet containing a single average dose of each of the above drugs would weigh 340 grains if the drugs are simply powdered—as they are claimed to be in Nature's Remedy. If they are represented by their extracts the tablet would still weigh about 70 grains. Yet each Nature's Remedy tablet weighs but 5 grains, of which only 3 grains is medicament! Of course, we should not expect a full dose of each of the drugs, and since there are ten of them, let us say that 1/10 *of a dose of each should* be present. The tablets *should* still weigh *34 grains, if* powdered drugs are present, and about 7 grains if the extracts are used. Since the seven named by the manufacturers are either not present at all or only in very small amounts, our consideration of dosage can be confined to aloes, cascara, belladonna root, and mandrake. Since the microscopic examination showed Nature's Remedy to be largely powdered cascara, the cathartic effect must be due to some very powerful drug since the tablets contain only about 3 grains of medicament. The dose of aloes is 4 grains or more, therefore there is scarcely room for even a moderate dose of aloes along with the cascara, unless it be present as aloin. Thus we cannot account for the active cathartic effect without assuming the presence of some powerful drug like podophyllin or aloin.

Nature's Remedy then is, essentially, aloes or aloin, cascara, and belladonna with, probably, podophyllin. This is such a common cathartic mixture that pills or tablets containing essentially the same ingredients can be purchased in almost any drug store. The manufacturers of these tablets direct the purchaser to take one every night for a week. They very kindly allow the sufferer (from the effect of the tablets) a few days to recuperate and then suggest that the week of torment be repeated and if this is survived, another few days of rest is allowed before another round of torture and so on "until the bowels become strong enough to do their work." The ill effects of such violent treatment have been enlarged upon so often that it is pernicious to suggest that such a course of treatment be followed.

Correspondence

OCCURRENCE OF PAROTITIS IN INFLUENZAL PNEUMONIA

To the Editor:—I was very much interested in the communication from Dr. Thomas F. Reilly, entitled "Three Signs of Some Value in the Diagnosis of Unusual Cases of Influenza" (The Journal, Dec. 7, 1918, p. 1935). That part of the article describing involvement of the orifice of Steno's duct was particularly interesting. In two cases of pneumonia following influenza that I treated recently, I paid close attention to the involvement of Steno's duct, and I am able to corroborate the findings of Dr. Reilly. In both of the cases there was a typical lobar pneumonia temperature, and the crisis was reached on the ninth day. The interesting point about the two cases was the occurrence of parotitis, which appeared with the crisis. One case developed overnight, and the swelling was as pronounced as in that of a case of specific parotitis. The following afternoon, in speaking to the nurse in attendance on the other patient, I remarked about having a case complicated by mumps. She said that her patient had a swelling under the right ear. On examination I found another case of parotitis. Both patients suffered intense pain for the first twenty-four hours, and required morphin; but with constant application of the ice cap the temperature, which rose after the swelling, became normal, and recovery was uneventful.

J. Maxey Dell, M.D., Gainesville, Fla.

AN EARLY REFERENCE IN MEDICAL LITERATURE TO THE RELATION BETWEEN FOCAL INFECTION AND ARTHRITIS

To the Editor:—In the summer of 1914, while on a medical pilgrimage originally planned for European centers, but unexpectedly diverted to Boston (I was one of those who took passage on the North German Lloyd steamer *Kronprinzessin Cecilie* for Plymouth, England, July 29, and the impending outbreak of war, August 3, determined a change of course of this vessel westward to Bar Harbor), I chanced to be in the office of Dr. George Shattuck, where, in looking over an edition of Dr. Benjamin Rush's "Medical Inquiries and Observations," which he had just acquired, my attention was drawn to the following case history appearing under the caption, "An Account of the Cure of Several Diseases by the Extraction of Decayed Teeth":

> Some time in the month of October, 1801, I attended Miss A. C., with a rheumatism in her hip joint, which yielded for awhile to the several remedies for that disease. In the month of November it returned, accompanied with a severe toothache. Suspecting that the rheumatic affection was excited by the pain in her tooth, which was decayed, I directed it to be extracted. The rheumatism immediately left her hip and she recovered in a few days.
>
> I cannot help thinking that our success in the treatment of all chronic diseases would be very much promoted by directing our inquiries into the state of the teeth in sick people, and by advising their extraction in every case in which they are decayed. It is not necessary that they should be attended with pain, in order to produce diseases, for splinters, tumours and other irritants before mentioned often bring on disease and death, when they give no pain and are unsuspected as causes of them.

The edition of Rush in which this appeared had belonged formerly, I believe, to Dr. James Jackson, subsequently to the late Dr. Arthur T. Cabot, from the sale of whose library it was secured by Dr. Shattuck. Two years later, on the occasion of a visit to Sir William Osler at Oxford, I noticed a set of these volumes in his library and called his attention to the account of the case recorded above. It is due largely to his suggestion that I write to The Journal to invite attention to the occurrence of this early reference to focal infection and secondary arthritis. It may be of literary interest to note here that the delay to do so until now has been due to inability to find the reference again in any of the editions of Rush that I had an opportunity of consulting while abroad. A search for it in the libraries of the Royal College of Surgeons, the Royal Society of Medicine and the British Museum was unavailing, and not until recently did I discover why this reference could not be located in any of the editions accessible to me in London. Through the courtesy of Lieut.-Col. Fielding H. Garrison, M. C., U. S. Army, I was enabled to see the editions of Benjamin Rush's "Medical Inquiries, etc.," in the Surgeon-General's Library at Washington, and then I found that the case history referred to had originally appeared in 1803, in the "Medical Repository" (Vol. VI, Art. XII, p. 285) in the form of a letter written by Rush to the editor. Therefore, only the editions of "Medical Inquiries, etc.," published subsequent to 1803 contained the reference, namely, those of 1815 and 1819. It appears on p. 199, in Vol. I, of the 1815 edition, and on p. 197, Vol. I, of the fifth edition, published in 1819.

F. L. Pleadwell, Capt., M. C., U. S. Navy.

MADURA FOOT IN CUBA

To the Editor:—In Queries and Minor Notes (The Journal, No. 16, 1918, p. 1684) appeared a communication about Madura foot (mycetoma) in the United States. In the bibliography appended to the note, no mention is made of a very detailed monograph about the matter, written in 1901 by Drs. Antonio Díaz Albertini and Cárlos M. Desvernine, and read before the Tercer Congreso Pan Americano, held in Havana in February, 1901, and published in the *Revista de Medicina Tropical,* May, 1901, and reprinted in the *Boletín "Sanidad y Beneficencia,"* March-April, 1918, pp. 319-330, in the Section "Historia Médica de Cuba," by Dr. José F. de Pazos, with the photographs of the two cases studied. These cases are of interest as being the first cases of Madura foot found and described in Cuba. Dr. Vincent of Val de Grâce, who studied the histologic findings, sent to him by Dr. Díaz Albertini, concluded that:

1. The photographs were surely of cases of Madura foot.
2. The histologic preparations showed the streptothrix, with the same characters as those revealed in examinations made by him of pus from the nodules of Madura foot.
3. The preparations sent to him by Drs. Albertini and Desvernine were the same as those prepared by himself.

In Cuba, it seems probable that *Discomyces madurae* (Vincent, 1894) was present in negro slaves when the Spanish governed the island. At present it is very rare: since the report of Albertini and Desvernine, there have not been found any other cases of Madura foot in Cuba. Other species of *Discomyces,* such as *Discomyces asteroides* (Eppinger, 1890), have been found two times by Dr. Pazos in the sputum of tuberculous patients. *Discomyces minutissimus* (Guchardt, 1859) is very frequent in cases of erythrasma in Cuba. Dr. Pazos also has found *D. bovis, D. israeli* and *D. thibiergii* in cases of abscess of the inferior maxilla in Cuban patients.

Dr. W. Octavio Montoro, Havana, Cuba.
Chief of Press and Publications, Secretaría de Sanidad.

"PHYSICIANS' EXEMPTIONS FOR INCOME TAX"

To the Editor:—Your comments on "Physicians' Exemptions for Income Tax" (The Journal, Feb. 22, 1919, p. 576) were very instructive—in my own case, a great deal more so than you could have imagined when you published the editorial.

What did it teach me? First, of course, that I have been paying needlessly money as a tax on things that were exempt. But after I had worked out my tax papers and scanned them at leisure, it taught me this much more: I had *imagined that* I had about a 7,000 dollar practice, being a "true physician, and a poor bookkeeper." On seeing the actual figures, I found that it ran about $5.300 total collections. After deducting actual business running expenses, I was shocked to find my "7,000 dollar practice" dwindle to a paltry $3,400.

On further observation, I have been shocked at the items of expense. My automobile upkeep is the worst shock. I also keep a horse, which I use when the snow blocks the roads; but as the cold rides exposed to the weather are less inviting than the warm interior of my car, I have often been tempted to plow through the snow with the car. My gasoline consumption has been about 15 miles to the gallon in the summertime; but on investigation I find that a gallon, costing here 40 cents, takes me through the snow less than 5 miles, so hereafter, as the horse eats as much whether I use him or not, I shall use the horse, when it is only a matter of comfort.

Thanks for the lesson you have taught me, and the amount, many times the cost of The Journal, that you have saved me at one sitting.

E. S. Pomeroy, M.D., Winter Quarters, Utah.

GREEK ROOTS AND ENGLISH WORD FORMATION

To the Editor:—I have read with interest the editorial on page 654 of the issue of March 1 entitled "Food and Bacteria—the New Bromatherapy." My classical ear was somewhat offended by this term. As you used the correct Greek derivation in the first column on page 655 in the word "bromatology," the contrast with the second word therefrom, namely, bromatherapy, was acutely accentuated. Since the genitive is always used in introducing English words of Greek origin, I hardly need inform your classical editor that "bromatos" is the correct form for compounded words. In order that you may not fall into similar error in the future, I am taking the liberty of sending you a reprint of my essay on Bromato-Therapy.

Yours in the interest of Homer and Socrates, Æsculapius and Hippocrates, H. W. Wiley, M.D., Washington, D. C.

[Comment.—When our correspondent states that "the genitive is always used in introducing English words of Greek origin" the philological ear is offended, for such is not the case. Only the genitive *stem* is used, namely, in this case βρωματ-, and not the genitive form βρώματος. There are in our medical dictionaries a number of words containing the same error pointed out by the writer, for example, "hemapoiesis," "somatome" and "bromatoxism," found in the "American Illustrated Medical Dictionary." However, we are grateful for the criticism, and are glad to know that we have in our old friend an earnest advocate of linguistic purity in the matter of word formation when Greek roots are involved.—Ed.]

German Substitutes in War Surgery.—The *Medical Supplement* compiled by the British Medical Research Committee gives an account of some of the substitutes for surgical materials employed by the Germans during the war. Many soap substitutes were tried, but the soda preparations seem to be the only successful ones. Spirits of wine (containing 70 per cent. alcohol) was used for washing the hands and instruments, care being taken to recover the alcohol. No satisfactory substitute for glycerin was found. American petrolatum was substituted by a jelly distilled from petroleum stiffened with ozokerit. Synthetic rubber was employed in small quantity, but its cost was very high. Rubber recovered from worn out articles and worked over again was not found satisfactory because it was not found sufficiently elastic, but was used for operating gloves with one half pure rubber or synthetic rubber. Rubber drainage tubes were replaced largely by glass and regenerated rubber. Rubber bulbs for nasal and dental work were satisfactorily replaced by bellows-like apparatus. Rubber bands were replaced by spiral springs. Vulcanite dental plates were replaced by aluminum. Steel for instruments degenerated and the nickel plating was thinner and wore off sooner. It was replaced by cobalt, which was worse, wore off sooner and blackened on boiling. Bandage material was replaced by wood fiber, paper, nettle fiber, etc. Wood fiber bandage is strong if dry, but can be sterilized only in steam and tears easily when wet.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arizona: Phoenix, April 1. Sec., Dr. Allen H. Williams, 219 Goodrich Bldg., Phoenix.

California: Los Angeles, March 17-20. Sec., Dr. C. B. Pinkham, State Capitol, Sacramento.

Colorado: Denver, April 1. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

District of Columbia: Washington, April 9-11. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Idaho: Pocatello, April 1-2. Sec., Dr. Ray H. Fisher, Rigby.

Iowa: Iowa City, March 24-26. Sec., Dr. G. H. Sumner, Capitol Bldg., Des Moines.

Minnesota: Minneapolis, April 1-4. Sec., Dr. T. S. McDavitt, 741 Lowry Bldg., St. Paul.

Montana: Helena, April 1. Sec., Dr. S. A. Cooney, 205 Power Bldg., Helena.

National Board of Medical Examiners: Philadelphia, June 2-7. Sec., Dr. J. S. Rodman, 1310 Medical Arts Bldg., Philadelphia.

New Mexico: Sante Fe, April 14-15. Sec., Dr. W. E. Kaser, East Las Vegas.

Oklahoma: Oklahoma City, April 8-9. Sec., Dr. J. J. Williams, Weatherford.

Rhode Island: Providence, April 3-4. Sec., Dr. B. U. Richards, State House, Providence.

Utah: Salt Lake City, April 7-8. Sec., Dr. G. F. Harding, Templeton Bldg., Salt Lake City.

Florida December Examination

Dr. W. M. Rowlett, secretary of the Florida Board of Medical Examiners, reports the written examination held at Miami, Dec. 2-3, 1918. The examination covered 7 subjects and included 70 questions. An average of 75 per cent. was required to pass. Of the 15 candidates examined, 11 passed and 4 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
University of Georgia	(1912)	75
Rush Medical College	(1900)	84.3
Louisville Medical College	(1879)	82.5
University of Louisville	(1898)	86.8
University of Maryland	(1902) 88.3; (1918)	81.3
Kansas City Medical College	(1888)	75
St. Louis Medical College	(1889)	83.4
Albany Medical College	(1904)	83.1
Jefferson Medical College	(1889)	85.5
Tennessee Medical College	(1900)	87.5
FAILED		
University of Arkansas	(1907)	67.1
Kentucky School of Medicine of Louisville	(1894)	67.8
Meharry Medical College	(1917)	65.5
University of Havana	(1896)	72

Colorado January Examination

Dr. David A. Strickler, secretary of the Colorado State Board of Medical Examiners, reports the written examination held at Denver, Jan. 7, 1919. The examination covered 8 subjects and included 80 questions. An average of 75 per cent. was required to pass. Of the 8 candidates who took the physician's and surgeon's examination, 4, including 1 osteopath, passed, and 4 osteopaths failed. Twenty candidates were licensed on credentials. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Chicago Hospital College of Medicine	(1918)	88.2
University Medical College of K. C.	(1903)	81
University of Toronto	(1911)	75.3

College	Year Grad.	No. Licensed
LICENSED ON CREDENTIALS		
Chicago College of Medicine and Surgery	(1910)	1
Rush Medical College	(1902)	1
Kansas Medical College	(1897)	1
Hospital College of Medicine	(1906)	1
Kentucky School of Medicine of Louisville	(1893)	1
Tulane University	(1897)	1
University of Maryland	(1903)	1
Harvard University	(1895) (1918)	2
Marion-Sims College of Medicine	(1893)	1
St. Louis College of Physicians and Surgeons	(1909)	1
University Medical College of K. C.	(1906)	1
John A. Creighton Medical College	(1917)	1
University of Nebraska	(1904)	1
Columbia University	(1903)	1
Medical College of Ohio	(1896)	1
Starling Medical College	(1896)	1
Medical College of the State of S. C.	(1913)	1
Baylor University	(1912)	1
McGill University	(1890)	1

Book Notices

The Autonomic Functions and the Personality. By Dr. Edward J. Kempf, Clinical Psychiatrist, Saint Elizabeth's Hospital, Washington. Nervous and Mental Disease Monograph Series No. 28. Paper. Price, $2. Pp. 156. New York: Nervous and Mental Disease Publishing Company, 1918.

The author states that this is an endeavor to substitute a "dynamic mechanism that can be visualized by the student" for the *libido* of Freud and Jung. One is tempted to believe that it is an attempt by a freudian to shield the *libido,* in which he believes, from the obloquy of numerous critics and skeptics, by putting on it an organic dress as yet sufficiently new and vague to be quite inoffensive. Whether or not he succeeds is for the reader to decide. As the title indicates, the monograph is an essay on the relations of the autonomic nervous system to psychic processes and personality. But it is more—or less. The thesis sustained is that "the autonomic apparatus dominates the organism and that the affections have their origin in the peripheral functions of this apparatus." The argument is divided into three steps: Part I tries to show that since the process of atrophy of disuse tends to eliminate useless material and movements, and that growth of the useful tends to make permanent necessary material and movements, the architecture of an animal should reveal in a general but reliable manner the fundamental law or process that determined the peculiar form of its existence. Part II is devoted to a consideration of such physiologic data as are suited to demonstrate the dominant nature of the autonomic apparatus. The interpretation of (1) the continuity of postural tonus of the striped muscles as the source of a continuous kinesthetic stream, and of (2) the unstriped muscles as the source of a continuous affective stream, is based principally on the physiologic researches of Sherrington and Langelaan, and on introspective observations of spontaneous reactions. Part III is the primary effort of the monograph, namely, an attempt to obtain recognition for the "fact" that in the higher organisms an affective sensorimotor system (autonomic) exists which created and uses the cerebrospinal or projicient sensorimotor system as a means to keep in contact with the environment in order that the autonomic apparatus may fulfil its biologic career. The monograph is well written, with sincerity, not to say enthusiasm, and contains some admirable information with much ingenious speculation. Undoubtedly it will be of interest to those occupied with the subject it covers.

Glaucoma: A Textbook for the Student of Ophthalmology. By Robert Henry Elliot, M.D., B.S., Sc.D. Cloth. Price, $7.50. Pp. 546, with 158 illustrations. New York: Paul B. Hoeber, 1918.

It is safe to say that there has been more advance in the diagnosis and treatment of glaucoma in the past ten or twelve years than in any similar period since the introduction of miotics. A textbook by one who has had much to do with this advance, giving in an able manner a review, summary and critique, is most welcome at this time. Special attention is given to Arthur Thompson's theory of the passage of the aqueous fluid from the anterior chamber into the canals of Schlemm by means of the "suction-pump" action of the pectinate ligament, in which it and the scleral spur are first pulled backward and toward the axis of the eye by contraction of the ciliary muscle, and then moved outward and forward as it is relaxed. In the chapter on etiology, much emphasis is placed on matters pertaining to the dimensions of the eye and the growth of the lens throughout life, as developed by Priestly Smith, and on heredity. Arteriosclerosis is discredited as a cause. The importance of the tonometer as a means of diagnosing is fully recognized by the author, but he lays even more stress on its constant use as a means of prognosis. The last third of the book is devoted to treatment, medical and surgical. The author is opposed to the use of miotics in general and pleads for early operation, quoting de Wecker: "If miotics have never cured a case of glaucoma, they have prevented many glaucoma patients from being cured." De Wecker, too, is credited with having been the first to appreciate the important rôle of the filtering cicatrix in iridectomy cases. The older masters, including von Graefe and de Wecker, were largely dependent on iridectomy, yet their writings do not make out a strong case for it. Naturally Elliot gives a careful description of his own corneoscleral trephine procedure, with its special feature of splitting the cornea from 0.5 to 2 mm. toward the center of the cornea to avoid cutting through any iris root adhesions, etc. But he also gives ample place to the operations of Lagrange, Herbert, Holth and Fergus. Among complications, Elliot gives a good deal of attention to "quiet" iritis. He has had no cases of "late infection," and thinks they may be avoided by thick-based flaps. So much concerning glaucoma is still unsettled that every one is entitled to his own opinion; but the author scarcely gives enough consideration to certain views manifestly opposed to his own. For instance, Jaeger and Schweigger, as well as Schnabel, and of late years von Hippel, have held that there is in glaucoma a "genuine atrophy" of the optic nerve independent of tension; yet of these authorities only Schnabel is quoted. He apparently feels that this situation is met by the statement that the atrophy which continues in some cases after normal tension has been restored is due to some "toxic or other influence." But this explanation is so inadequate as almost to beg the question. So far as we are aware, glaucoma alone, and no other disease, is known to have been present in these cases. Posey's valuable contribution on the use of miotics is not mentioned. Many will be unable to dismiss the bogey of "late infection" after trephining as easily as Elliot does.

By far the most interesting part of the book is the author's extended presentation of the newer intensive studies of the central fields of vision, Bjerrum's arcuate scotoma, going from the blind spot toward the fixation point, Roenne's nasal step, Seidl's sign, etc. He gives an ample discussion of the various theories of the origin and technic of taking such fields, including a description of a special scotometer of his own, and in general he emphasizes once more the wide and growing diagnostic and prognostic significance of these matters.

Paper Work of the Medical Department of the United States Army: A Guide for Administrative Work. By Ralph W. Webster, M.D., Ph.D., Major, Medical Corps, U. S. Army, Instructor, Basic Military Course, Camp Greenleaf. Approved for Publication by Direction of the Surgeon-General of the U. S. Army. Cloth. Price, $5. Pp. 541. Philadelphia: P. Blakiston's Son & Co., 1918.

In this book Dr. Webster has brought together, for the use of medical officers, the most important papers with which they are confronted while attached to organizations in the United States Army. The book is addressed particularly to reserve officers, to whom such a book no doubt would have been of great service had they continued to serve with troops during the recent war. The volume is replete with facsimiles of forms correctly filled out and with numerous suggestions as to the saving of time and trouble in taking care of these forms to prevent their being returned by headquarters for revision or modification. Had the war continued, this book would have ranked as a medical military "best seller"; as it is, it will be extremely useful to those medical officers taking part in the demobilization of the troops.

Clinical Microscopy and Chemistry. By F. A. McJunkin, M.A., M.D., Professor of Pathology in the Marquette University School of Medicine. Cloth. Price, $3.50. Pp. 470, with 131 illustrations. Philadelphia: W. B. Saunders Company, 1919.

The subjects indicated by the title of this book are presented from the laboratory standpoint, clinical descriptions and discussions being left out; hence much of the volume deals with laboratory technic, though the relations of examined materials to the tissues of the body are kept well before the mind of the reader. More than microscopy and chemistry is dealt with, however, the book possessing especially a comprehensive chapter on necropsy technic. The inclusion of small details of technic in the descriptions of laboratory procedures, useful details sometimes omitted from textbooks, and the clearness of the illustrations of apparatus, enhance the value of this volume for instruction of classes and for use as a reference book for routine laboratory technic.

Medicolegal

Treatment of Hemorrhoids by Injection—Pain and Negligence

(Thomas v. Register (S. C.), 96 S. E. R. 517)

The Supreme Court of South Carolina reverses a judgment obtained by the plaintiff, with direction to enter a nonsuit for the defendant, in this action against a physician for an alleged tort or wrongful act to the person, for which a verdict was returned in favor of the plaintiff for both actual and punitive damages. The court says that the alleged tort arose out of the treatment of the plaintiff by the defendant for hemorrhoids. The charge was that the treatment was both negligent and wilful. But the court finds no room to find from the testimony that the defendant was either negligent or wilful in what he did. The only negligent act suggested by the plaintiff's counsel at the bar was the persistent treatment of the patient, notwithstanding the pain that the treatment gave the patient. No testimony was offered that hemorrhoids could be treated without pain. Negligence is not a reasonable inference from the bare fact that pain accompanied the treatment.

There was no testimony tending to prove that the compound injected, or that the instrument used for the injection, was unfit. On the other hand, one of the plaintiff's expert witnesses testified that he "had heard of treatment by injection, and that some reputable physicians use the same now." Moreover, counsel was unable to suggest at the bar any act or any utterance of the defendant that pointed to his wilfulness, and the testimony showed none such. The trial court ought to have directed a nonsuit, and must yet do so.

The trial court excluded all testimony tending to show specific instances in which other persons had been benefited by the treatment that was administered to the plaintiff. The complaint alleged that "the defendant is commonly called and designated as a 'quack and an impostor,' and that he is unskilled and unlearned in his profession, and was and is wholly incapable of relieving or curing piles in and by the manner of treatment which he applied to the plaintiff, and that the defendant well knew such fact." The issue, then, that the plaintiff tendered by his pleading was that the remedy was specious, and the defendant knew the fact. If it be true that the defendant applied the same remedy to others than the plaintiff, which others had a like affliction, and with helpful results, that would tend to disprove the plaintiff's allegation. The testimony was competent.

Effect on Appeal of Death of Physician Enjoined from Local Practice

(Branscome v. Cunduff (Va.), 96 S. E. R. 770)

The Supreme Court of Appeals of Virginia, in dismissing the appeal of defendant Branscome, without a decision on the merits of the case and without costs of either party, on account of his death, says that the defendant, a practicing physician, sold and conveyed his home to the plaintiff, residing and practicing in the same town. The deed expressed a money consideration of $2,250, and contained a provision that for the same consideration the defendant agreed not to locate again within the radius of 15 miles of the town, as a practicing physician. The defendant moved away, but returned within a year from the date of the deed, took up his residence near the town, and resumed the practice of his profession. The plaintiff thereupon brought this suit for an injunction. The result was a decree of the lower court whereby the defendant was perpetually enjoined from practicing medicine and exercising his profession as a practicing physician within a radius of 15 miles from the town. From that decree this appeal was allowed. But after the cause was argued and submitted in the supreme court of appeals, the defendant died. It was insisted by counsel for the appellant that in this particular case the controversy ought to be decided, in order to settle the question of costs, the amount of which was said to be considerable. But the issue on which the cause came to this court had by the death of the defendant become a purely moot question, and nothing remained for the court to do, except to enter an order dismissing the case without costs to either party. This is the settled practice in Virginia and elsewhere generally.

Purpose for Which Roentgenograms May Be Used

(Russell v. Borden's Condensed Milk Co. of Utah (Utah), 174 Pac. R. 633)

The Supreme Court of Utah says that in this personal injury case it was contended that the trial court erred in admitting in evidence certain roentgenograms showing the condition of the plaintiff's hip and hip joint. It was insisted that the roentgenograms had a tendency to mislead the jurors, who were merely laymen and thus possessed no knowledge respecting the injuries to the bone or to the hip or hip joint. If the roentgenograms had been introduced for the purpose indicated by counsel, there would be much force to their contention. A jury of laymen possessing no knowledge or experience respecting the bones and injuries thereto might easily be misled by a mere roentgenogram, by which at the best merely the outline of the bone can be shown. The roentgenograms, however, were not introduced for the purpose indicated by counsel. They were used by the physicians in illustrating their evidence, and were fully explained, and were introduced in evidence only as affording a fuller and clearer understanding by the jury of the physicians' testimony respecting the condition of the plaintiff's injured hip and hip joint. The court committed no error in receiving the roentgenograms for the purpose for which they were received and used.

What the Law Requires of a Physician

(Hesler v. California Hospital Co. et al. (Calif.), 174 Pac. R. 654)

The Supreme Court of California, in reversing a judgment for $2,500 damages that was obtained against the hospital company and the physician it assigned to the case, for alleged malpractice in the treatment of a cold that developed into pulmonary tuberculosis, says that the jury was given, among other instructions, the following:

> 5. To sustain an action it is not necessary to establish gross culpability; mere evidence of want of proper or ordinary care or attention and advice in the discharge of duty by a physician is sufficient to take the case to the jury. 6. Civil malpractice may be either active or passive. It is active when a certain course of treatment is adopted and followed which is not sustained by authorities; it is passive when those things in treatment are omitted which should have been done in order to obtain a result approximating to perfectness. 9. As a general rule, he who undertakes for a reward to perform any work is bound to use a degree of diligence. attention and skill adequate to the performance of his undertaking; that is, to do it according to the rules of the art. 10. The physician must give proper instructions to his patient how to take care of himself, and what diet to adopt; and in case the physician fails to give these instructions he is liable for any injury that results from such failure.

Instruction 5 is to the effect that a physician is liable in damages if he fails to give "proper" advice to his patient. Instruction 10 reiterates this doctrine. Instruction 6 gives the jury to understand that a physician is guilty of malpractice, and liable in damages, if, in treating a patient, he fails to do anything necessary to obtain an approximately perfect result. The law does not require that the instructions and advice given by a physician to a patient should be at all events and beyond question "proper," or that his treatment should be certainly such as to obtain an approximately perfect result. It requires only, first, that he shall have the degree of learning and skill ordinarily possessed by physicians of good standing practicing in that locality; and, second, that he shall exercise reasonable and ordinary care and diligence in treating the patient and in applying such learning and skill to the case. The law takes cognizance of human weakness and liability to err in the application of skill and learning, and it requires only the exercise of reasonable and ordinary care and diligence to avoid error. These instructions require more: they require that the advice given shall be "proper," which implies that no error shall be committed; they require that the physician shall do everything necessary to be done to produce an approximately perfect result; that he guarantees that his treatment shall be of that quality; whereas, the law demands only that he use reasonable care to attain such approximate perfection. Instruction 9 declares that the physician is bound to use, and of course to have, a degree of skill "adequate" to the performance of his undertaking. The law requires that he have the degree of skill ordinarily possessed by reputable physicians practicing in that locality. This may or may not be "adequate" to the performance of his undertaking, according to the meaning to be given to the word "undertaking." If it was intended to mean that he undertakes a cure, or to produce a result approximating perfection, as stated in Instruction 6, or that he undertakes to use the highest possible degree of skill, the standard is higher than the law requires. The instruction is uncertain on this point, and it may have misled the jury.

The court below in other instructions (not given in the opinion) stated the rule by which the defendants were bound accurately and clearly. There was a clear conflict in the instructions. The supreme court is unable to determine which set of rules the jury followed. The case of the plaintiff on the merits, at best, was not strong. The court cannot say that these instructions were not injurious to the defendant, and did not improperly control the deliberations of the jury in rendering a verdict.

Society Proceedings

FIFTEENTH ANNUAL CONFERENCE OF THE COUNCIL ON MEDICAL EDUCATION OF THE AMERICAN MEDICAL ASSOCIATION

Held in Chicago, March 3, 1919

Dr. John M. Dodson, Chicago, in the Chair

Problems in Medical Education

Dr. John M. Dodson, Chicago: By means of the effective organization of the American Medical Association, the medical profession of the United States was able to render a magnificent response to the call of the nation for medical officers in the world war, now happily suspended, and its closing chapters being written by the peace congress sitting in Paris.

We ought to be engaged now in the collection of all the necessary data for the coming historian of this epoch. The officers and faculty of every medical school owe to themselves, to their students and alumni, to the medical profession, and to posterity to see that there is gathered and carefully recorded at once, while the events are fresh in mind, all the essential facts pertaining to the participation of the school in the war.

To meet the possible demand for many thousands of medical officers, it seemed necessary to expedite the matriculation and graduation in medicine of as many students as possible. At the request of the Surgeon-General, the time requirement for admission to medical schools was reduced from two years to one and one-third years. Is there any reason why this lower standard should be continued, now that the exigency created by the war no longer exists? The two years' requirement seemed all too short, and that now is the legal requirement for licensure in thirty-two states.

The continuous session, on the four quarter plan, has been in effect for nearly twenty years in at least one medical school, though it had been impossible for a student to complete the legal requirement of attendance in less than forty-two months, because of the regulations of some of the state boards of medical examiners. Is there any logical reason why the student should not be allowed to utilize the summer months in full-time medical work in residence, and thus complete the present requirement of four sessions in three calendar years, his year of internship in a fourth year, and so enter into active practice a year earlier than has been possible under previous regulations? The ruling of the state boards that "twelve months shall intervene between the beginning of any recognized session and the one succeeding it," or that "no two sessions shall begin in the same twelve months" (the restriction has been variously worded), was first promulgated many years ago, under conditions and to meet abuses that no longer exist. Under the four quarter scheme, seven weeks may be provided for vacations, so that attendance on the four quarters is no hardship for the student in good health who desires to avail himself of the privilege.

If approval of the plan is desirable, the state boards should revise their rulings or have the laws amended, if necessary.

Opinions may differ as to the amount of special training that may be indispensable to efficient service in the Medical Corps of the Army, but all will agree that a certain minimal degree of such training is essential, and no future war ought to find the medical profession so unprepared for military service as we were for this war. Moreover, the discipline and training essential to prompt and effective organization and operation of large groups of medical men, such as may be called for in a great earthquake, flood, fire or other great catastrophe, can be secured most effectively by military methods.

The scheme of organizing groups of physicians representing several special lines of practice has been growing steadily in this country for several years. To a degree never before approached in army medical practice, the several specialties were recognized in the medical corps of our army in this war. In the post and base hospitals, both at home and abroad, the medical work was performed by a carefully selected group of specialists, provided with ample facilities and appliances of all sorts for thorough work in diagnosis and treatment. What a source of consolation and confidence this was to those who had sons in the service, liable to be in need at any moment of the most skilled medical attention. The thousands of American physicians who were engaged in these hospitals, and who experienced the profound comfort and satisfaction of thorough, accurate, scientific work, possible only in such groups of consulting specialists, are little likely to return with equanimity to their former custom of attempting individually to cover the whole field of medicine.

Two questions are suggested by these facts: First, should our scheme of medical education be altered so as to encourage and provide for the education of our undergraduates directly for a special line of practice—internal medicine, surgery or ophthalmology, etc.—or should we continue to insist that every student of medicine should first secure a reasonably broad, comprehensive knowledge of general medicine, turning his attention to some exclusive line only when he has had considerable practical experience—at least a year or two of hospital training—in the general field? Second, ought not the public to demand of any physician who presents himself to the community as a "specialist" in any particular field, that is, as one possessed of special, superior knowledge, experience and skill, some proof of such ability as would be given by a license to practice ophthalmology, surgery or what not, issued by a board of competent examiners?

Another phase of medicine that has been brought into great prominence by the experiences of the war is preventive medicine, which has demonstrated its great possibilities as contrasted with curative medicine. For the first time in the history of warfare, with the exception of the Japanese-Russian War, deaths of soldiers from disease have been less than those from the casualties of combat. Had it not been for the sudden onslaught of the most fatal pandemic in modern times, the mortality from disease would have been almost unbelievably low. And this was made possible by the thorough, painstaking enforcement of the hygienic and sanitary methods of modern preventive medicine, which proved effective even under the difficult and distressing conditions of trench warfare. Never has the time-worn adage been more strikingly illustrated that "an ounce of prevention is worth a pound"—aye, many pounds—"of cure."

In five states a year of hospital training is a prerequisite for licensure, and three other states are soon to demand the same preparation; six medical schools now graduate students only after the successful completion of such a fifth year, and two others are soon to do likewise. The very rapid increase in the number of hospitals in the United States has insured a place for every medical graduate. On the other hand, the conditions of intern service in these hospitals are widely divergent, and in very few of them ideal. The hospital internship, like the so-called training schools for nurses, is still in many hospitals merely a mean device for securing cheap help. In the interests of the patients, the students, the medical attendants and the community at large, one of the greatest needs of our time is for a better coordination of the hospitals and the medical schools.

This suggests many questions. Should this fifth year be primarily under the control of the licensing bodies—the boards of medical examiners—or of the men who are concerned with the education of the student—the faculties of the medical schools?

There seems little hope, all things considered, for universal reciprocity between the medical boards of our forty-eight states with their widely varying standards of examination. But some more sane and equitable method of insuring to every capable practitioner of medicine the right to practice anywhere in the Union, and to move without embarrassment at any time from one state to another, such as is furnished by the National Board of Medical Examiners, is an imperative need.

Recent Progress and Further Needs in Medical Education

Dr. N. P. Colwell, Chicago: There are now eighty-five medical colleges, of which eighty, or 94 per cent., require for admission two years of work in a college of arts and sciences, as compared with only 2.5 per cent. of all colleges holding to that requirement in 1904. And this requirement is not "on paper" only, since these colleges are voluntarily furnishing the Council with lists of the students admitted, together with statements regarding their preliminary qualifications, so that the Council can verify these qualifications, should question in regard to them arise.

Considering the character of the majority of medical schools prior to 1904, it is not so surprising that, according to reports, many of the physicians called into service may have been lacking in a knowledge of the specialties, and that some lacked a knowledge even of the fundamentals of medicine. Every one knows that there is still great room for improvements in teaching methods and in the thoroughness of instruction in our medical schools; but think how much greater would have been the deficiencies on the part of medical officers had it not been for the tremendous improvements in medical education and the many thousands of highly trained graduates who were turned into the medical profession during the last fifteen years.

Reports from seventy-three of the eighty-five colleges now holding sessions indicate that the total enrolment of medical students will be about 1,100 less than for the session of 1917-1918. The reduction is chiefly in the freshman classes. There were twenty-five medical schools which last fall for the first time exacted two years of collegiate work as the minimum requirement for admission, in which lower enrolments for the freshman classes would be expected. But the decrease was not due altogether to the higher entrance requirements, since, of the forty-eight colleges reporting which put into effect the higher requirements previous to 1918, thirty-nine report a decrease in the number of freshman students. The unusual decrease is largely due to the drafting or volunteering of premedical students during 1917-1918 for military service.

The total number of physicians in the United States, as shown by the sixth edition of the American Medical Directory, issued in 1918, is 147,812. The total population of the United States, according to the estimate of the Census Bureau for 1918, is 105,253,300. There is, therefore, one physician in the United States for every 712 people.

Two methods have thus far been devised for the continuous sessions in medical schools. One is the "quarter system," by which the year is divided into four terms of three months each, any three terms counting as a college year. The second plan is to divide the year into three terms of four months each, any two terms to count as a college year. The schools which have adopted the continuous session have so arranged their curriculums and provided the teachers that students who are physically able and who desire to do so may continue at their medical studies the year around. In their schools also, during any quarter, students may make up courses in which for any reason they have failed to complete without loss of an entire year. Delayed matriculation also will mean the loss of only one quarter instead of an entire year. The continuous plan also enables the institutions to care for a larger number of students, and it keeps an extensive teaching plant in continuous operation.

An improvement still greatly needed in medical schools is in the methods of clinical instruction of medical students. Students should be enabled to complete most of their didactic courses in the third year so that most, if not all, of the time in the fourth year may be devoted to clinical courses for groups of about six students each in the hospital wards. Each student should have a patient assigned to him, and under careful supervision should write the history, make the essential laboratory examinations, suggest the treatment and follow the progress of the case during the patient's stay in the hospital.

On the student's undergraduate clinical training depends the standard of clinical training which should be furnished in the intern year. The character of this training is best known to the medical college he attended and not to the state licensing boards. It is a desirable step for state licensing boards to require the completion of an internship in a hospital as an essential for the license; but the medical college is in the best position to select the hospitals in which its students should obtain their intern training and to supervise the work of the intern in such hospitals.

The Needs of Medical Education as Revealed by the War

Edward L. Munson, Brig.-Gen., M. C., U. S. Army: The nature of the conditions and ideas under which the old Medical Reserve Corps was organized had their influence on its medical standards and the medical examinations required for its enrolment. In general, it was composed of three classes: 1. The recognized leaders of the medical profession, who lent the weight of their well known names and great professional reputations to popularize the then new Reserve Corps; the abilities of these men were well known, and the examinations to which they were subjected were probably cursory. 2. A somewhat smaller class probably consisting of a personnel drawn from the average class of practitioner, such as constitutes the backbone of the medical profession of the country; here also the examinations required were none too rigid, but no professional difficulty later occurred as a result of any professional inefficiency on their part. 3. A not inconsiderable third class, composed of less well qualified men, some of whom enrolled for patriotic purposes and others perhaps by reason of the desire to possess a commission.

The medical officers who finally reached the medical training camps represented better than the average of the medical profession of the country, for these candidates had been subjected to several processes of *elimination*:

(*a*) They had to be invited to appear for examination by the Surgeon-General, and unless they appeared to be probably desirable, this invitation might not be forthcoming.

(*b*) They had to be graduates of reputable medical colleges, which ordinarily eliminated men coming from institutions of poor character.

(*c*) They had to be licensed to practice in the state in which they lived, which would exclude medical graduates who had been found later to be not thoroughly qualified.

(*d*) They had to be in the active practice of their profession, thereby excluding the failures in medical practice who were making their living by some other vocation.

(*e*) They had to pass an examination before a local board, which had to be satisfied with their professional, physical and moral qualifications. Here occurred the greater number of rejections, for the local board not only was in a position to test out qualifications by examination, but in many instances it knew the candidate personally or by reputation, and was well informed as to his antecedent activities and conduct.

(*f*) Before they were commissioned, the American Medical Association investigated and reported on their cases, to make sure that there was nothing in their career that should render undesirable their appointment as medical officers.

(*g*) Finally, the Surgeon-General had the right of rejection, which was exercised in the case of men who ultimately appeared from their papers to be not qualified for the service.

Thus a large proportion of the undesirables were excluded from service and never reached a medical training camp which dealt with an already selected class. That this selected class presented still further professional deficiencies invites reflection on the part of all those in charge of medical education.

The medical training camps acted as filters to determine and eliminate the unfit. Examining boards were appointed to examine all student officers, and to recommend for discharge all whom they found disqualified for service in any capacity.

For some time the recommendations of these boards were not fully accepted by the specialist divisions of the Surgeon-General's Office, which had card indexed the men whose reputations seemed to warrant their acceptance as specialists. So many were found to be overrated by their reputations that the specialist divisions finally agreed to make their appointments subject to the examination held by the examining boards at training camps. The number found not qualified was considerable. A few alleged specialists were even found unfit to practice any branch of medicine in the service. Others not qualifying were made available for general assignment. General reputation is not necessarily a criterion of qualification, and a large number of men, generally accepted as specialists, are not qualified as experts.

Another class was not qualified but was too good to be discarded summarily. Accordingly "salvage classes" were started, the members of which were systematically and intensely quizzed by expert quiz-masters. The men assigned to these salvage classes were bright and energetic enough, but for one reason or another had not kept up with medical progress. The subjects in which they were quizzed were only those in which they were found deficient. The reclamation course usually covered about three weeks, when the candidates were reexamined and nearly all qualified. The reclamation classes at Camp Greenleaf amounted to as much as 6 or 8 per cent. of the student officers' group.

The general professional qualifications of officers bore a close relation to the educational standards of the schools from which they graduated. But various instances were noted in which graduates of good schools made a poor professional showing. Medical schools should require a satisfactory psychologic rating for condidates for admission to a course leading to the degree of Doctor of Medicine, to make sure that they have the mental aptitude to qualify properly for it.

A very large proportion of alleged specialists were found to be only partly qualified. To render them properly qualified, special schools were organized which were staffed with the ablest professional specialists in the country. The courses were highly practical and intensive, and the student officers appreciated their great value.

I cannot forbear from expressing my admiration at the manner in which the profession in uniform adapted itself to conditions. Its members accepted cheerfully the results of the stock taking of their qualifications, even though the latter might not have been flattering, and cooperated in every way to remedy the defects thus made apparent. Their eyes were opened to any shortcomings of the profession as a whole, and it is safe to assume that their military experience has shaken them out of complacency, and given them new ideals and broader purposes. One of the results of the war will be a better and more competent medical profession, the members of which will look to the medical educators of the country to set high ideals and provide the facilities for their attainment.

The Medical Enlisted Reserve Corps and Its Relation to Medical Students

Frederick C. Waite, Capt., Sanitary Corps, U. S. Army: With the declaration of war there was an immediate stimulus to enlistment in the Medical Reserve Corps. While these enlistments were as reservists, they were in the majority of cases made with the expectation of an early call to active duty. These enlistments were made in large part in connection with the formation of units in the Medical Department. Under this plan fifty Red Cross and base hospital units were formed. The enlisted personnel of each of these units approximated 200 men. Some of these units constituted the first military forces to be sent overseas following the declaration of war, arriving in Europe several weeks in advance of the earliest Regular Army organizations.

The purpose of permitting medical, dental and veterinary students to enlist in the Medical Enlisted Reserve Corps, to be left on inactive status, was to enable them to complete their professional training in order that they might be available material for officers in the Medical Department of the Army.

The justification for inactive status, and the consequent delay in entrance on active military duty, was the greater service that would be later rendered to the Army as medical officers. It was a legitimate war preparedness measure to train soldiers to render a more highly specialized service, if the war should go on, than they could render if immediately drafted as ordinary soldiers. Previous to the announcement, Sept. 4, 1917, of the regulations permitting medical students to enlist in the Medical Enlisted Reserve Corps, however, a considerable number of medical students volunteered or were inducted into active service.

The plan of allowing graduates of well recognized medical schools to serve as interns in hospitals for one year had a double object. It aimed to develop better medical officers for Army service by this practical experience and to preserve the efficiency of the hospitals of the country for protection of the civilian community.

Such an intern after graduation either obtained a commission in the Medical Reserve Corps or enlisted as a private in the Medical Enlisted Reserve Corps. In either case he was placed by his local board in Class V, and exempted from the draft on the ground that he was already in the military service of the country.

The continuance of inactive status for the intern was conditioned on the performance of his duties in the hospital in a manner satisfactory both to the Surgeon-General and to the authorities of the hospital, which was established by reports from the hospital authorities.

This regulation necessitated a classification of the hospitals of the country. A questionnaire was sent out from the Surgeon-General's Office to those hospitals which, on information available from these sources, appeared to be eligible for approval as places in which to train interns for Army purposes.

The Desirability of Units of the Reserve Officers' Training Corps in Medical Schools

Horace D. Arnold, Lieut.-Col., M. C., U. S. Army: The object of the Student Army Training Corps was to educate and train a body of intelligent men in preparation for positions as commissioned officers in the Army. The Committee on Education and Special Training feels that the S. A. T. C. did not have a fair chance in collegiate institutions, owing to a number of conditions beyond control. The success of its vocational sections, when time enough had elapsed for the proper development of methods, was unquestioned. Yet it is true that if this work had been stopped at the end of a month or six weeks, the story would have been one of confusion and lack of adjustment, almost equal to that of the S. A. T. C. in medical schools. The Army is convinced that the introduction of the regular military life into a professional school, with a curriculum as crowded and complicated as that in medicine, is not practicable. Should the occasion ever arise again which would require medical students to be soldiers in service, while still continuing the study of medicine, I think you may count on the least practicable interference with the medical course.

In order to make this plan effective, physicians should have, in addition to the qualifications for civilian practice, at least the following qualifications: (1) a knowledge of military hygiene and sanitation; (2) a sufficient knowledge of Army organization and methods to enable them to procure supplies and to carry on the administrative functions of their positions; (3) a sufficient military training to enable them to command the soldiers of the Medical Department under their charge.

These requirements can best be met through training in units of the Reserve Officers' Training Corps established in medical schools, and in summer training camps. Owing to the crowded curriculum of the medical schools, such a plan of military training must be so arranged as not to interfere seriously with the regular course of study in medicine. In the contemplated plan, military drill will be given at the summer camps; the number of strictly military courses will be reduced to a minimum; and the necessary theoretical training for medical officers will be sought, as far as practicable, in the adaptation of the existing courses of the medical school to military needs. Physical training to the extent of two hours a week for the freshman and sophomore years of the medical course will be required of members of the R. O. T. C., but it is felt that this will be of such definite personal advantage to medical students that it might well be adopted by the school as a requirement for all students. In no way does the medical school ignore its own teaching more than in its usually complete neglect of provisions for the physical health of its students. The normal R. O. T. C. course is divided into a basic course, covering two collegiate years and one summer camp, and an advanced course, covering two collegiate years and two summer camps. The basic course should be taken, if possible, before the student enters the medical school; and an opportunity to do this is offered while he is taking the two years of the required premedical course, provided the college maintains an R. O. T. C. unit. The basic training in infantry or in any other arm of the service will be acceptable. Military drill during the academic year is not essential, as a sufficient amount of this may be obtained in the summer camp, which the student should attend during the vacation following his freshman or sophomore year.

The advanced course will be offered at the medical school. The physical training and the required courses in strictly military subjects will be given during the first two years of the medical course, and the two summer camps devoted to the military training of the Medical Department will come during the vacations following the freshmen and sophomore years. In this way the last two clinical years of the medical course will be left essentially free from interference from the military training, the only courses necessarily given during these years being the relatively short theoretical courses in military surgery and military medicine.

It is the intention of the committee to have the members of the R. O. T. C. unit, during the period of the summer camp following the sophomore year of the medical course, assigned to duty in Army hospitals. They will thus learn not only the military duties of officers and enlisted men in these organizations, but will get practical experience in nursing and the care of the sick that will be equally valuable for civilian practice.

The requirements for graduation from the R. O. T. C. are: (1) the completion of the basic course of the senior division, R. O. T. C., or its equivalent; (2) the completion of the advanced course, R. O. T. C., and (3) attendance at three summer camps. On graduation from the medical school and from the R. O. T. C., and on recommendation of the professor of military medicine, and provided he is at least 21 years of age and he agrees under oath and in writing to serve the United States as reserve officer for at least ten years from date of appointment, unless sooner discharged by proper authority, the student may receive a commission in the Medical Reserve Corps. *(To be continued)*

Japanese Red Cross.—The Red Cross organization in Japan had its beginning about 1889. Five years later there was a membership of 160,000 and a fund of about $2,000,000. As a result of the war with China the membership in 1898 had increased to 570,000 and the annual income was approximately $800,000. At present, according to the Red Cross *Bulletin*, the Japanese organization has more than a million and a half of members, each of whom has enrolled for ten years, and pays into the organization at least $1.50. The headquarters of the organization in Tokyo is housed in a splendid modern building.

Cutaneous Aspects of Tuberculosis.—A careful study of ten cases made by Stokes leads to the conclusion that while it is impossible at the present time to dogmatize on the existence of a tuberculous type of purpura, erythema multiforme or erythema nodosum, clinical and experimental evidence is collecting to show a close association between a tuberculous infection and cutaneous syndromes of the type mentioned. Whether the lesions themselves are due to the tubercle bacillus, whether or not their appearance signalizes a flare-up in the tuberculous focus, cannot as yet be definitely stated. It is possible that a nontuberculous infection which produces erythema complex may uncover the tuberculous focus, much as measles is known to do, and permit a lighting up of a lesion otherwise quiescent. Stokes believes that the purpuric erythematous and nodose lesions are cutaneous reactions to hematogenously distributed bacilli, deposited in a hypersensitive skin and originating in a tuberculous focus sometimes unrecognized perhaps for many years. Whether the tuberculous phase is the cause or the consequence, the frequent clinical association of the cutaneous symptoms with this disease loses none of its importance from the standpoint of diagnosis and therapy. Stokes urges that every case of purpura, and many cases of erythema multiforme, should be subjected to a preliminary survey for the possibility of tuberculous infection. Cases of erythema nodosum, whatever their type, should be subjected to periodic reexamination and observation. In the absence of a demonstrable source of pyogenic infection, and even in its presence, the possibility of tuberculous etiology should be entertained seriously and an antituberculosis hygiene considered.

Acute Bronchitic Emphysema in Influenzal Pneumonia.—Observation of 1,150 soldiers with epidemic influenza pneumonia at Camp Hancock has indicated that the disease as it occurred there differed so essentially in its pathology and course from lobar, bronchopneumonia or lobular pneumonia, according to the usual conception of these diseases, that Torrey and Grosh designated the condition as acute bronchitic emphysema. Certain conditions were invariably present, including an intense bronchitis and peribronchitis similar to that found in a previous epidemic of pure hemolytic streptococcus infection. There was also present from the first a destructive softening of the lung parenchyma. In addition to this there was always an early and persisting generalized pulmonary emphysema which frequently was the main factor in causing death by interference with the mass movement of the venous blood. These conditions were found in every case examined at necropsy. Except for frequent acute otitis media there were almost no complications or sequelae outside of the chest. The pulmonary emphysema, with consequent venous stasis, accounted for the cyanosis, epistaxis and fixation of the chest in the phase of extreme inspiration, with low stand of the diaphragm, which characterized these cases, and also accounted for the paradoxical physical signs in cases in which fluid developed in the chest.

Primary Carcinoma of Duodenum.—Head reports the case of a man, 74 years of age, well nourished, looking very anemic, who for seven or eight years had complained of ill-defined gastric symptoms, exhibiting at times periodic attacks of vomiting of large quantities of greenish material, with partially digested blood, whose physical examination revealed a high grade secondary anemia, without assignable cause, except the presence of blood in the vomit and in the stools. He also presented a hyperacid gastric content. No palpable mass was in evidence. He died with the symptoms of obstructive vomiting—namely, either a carcinoma high in the intestinal tract, below the stomach, or a duodenal ulcer with a carcinoma superimposed, causing obstruction by occlusion of the bowel.

The diagnosis of the case prior to necropsy was a duodenal ulcer, with carcinoma superimposed, producing a slow developing occlusion of the intestine not far from the pyloric opening. Necropsy disclosed a resistant mass at the lower curve of the duodenum and extending over into the third portion. The lumen was almost completely occluded by a cauliflower-like mass growing from the median and posterior wall. Microscopic examination of the tumor showed a typical adenocarcinoma of the papillary type. Infiltration extended deep into the muscular layer of the duodenum on its inner aspect. No gross or microscopic lesions in the suprarenals, liver, pancreas or lymph nodes around the celiac axis were in evidence.

Soldiers Infected with Hookworm.—The percentage of positive cases for all white troops examined by Frick was 11.5 per cent.; the percentage of positive cases in the colored troops was 1.1 per cent. The three principal states gave the following figures: Louisiana, 898 cases; Mississippi, 454 cases; Arkansas, 243 cases; from all other states, 126 cases. Hookworm apparently has no marked effect on the health of the great majority of these men. This may be due to the mildness of the infection or the fit condition of the men through training. A routine was followed from the beginning and carried through without variation.

The soldiers were sent to the base hospital in groups of twenty to 135, usually after the noon meal. Early in the afternoon they were given a dose of salts; at 5 p. m. a thin broth; at 6:30 p. m. more salts. The next morning at 6 a. m. a third dose of salts. At 8 a. m. and 10 a. m., 1 c.c. of oil of chenopodium. This was followed an hour later by an ounce of castor oil in orange juice. In the middle of the afternoon they were given some liquid nourishment and at 5 p. m. a full meal. The next morning, after breakfast, they were returned to their companies. The oil of chenopodium was poured into capsules or given on sugar.

Granular Tuberculous Conjunctivitis.—In the case cited by Paterson 2 drops of 1 per cent. solution of O. T. was instilled into the conjunctival sac and almost immediately a dilation of the conjunctival vessels could be seen and a sharp reaction followed. This treatment was continued for six doses, at about ten-day intervals, making in all eight treatments, with reactions, after which the conjunctiva showed little evidence of the disease. All symptoms had entirely disappeared, the only evidence of previous disease being a few fine granulations and slight reddening of the bulbar conjunctiva at the extreme inner canthus. The palpebral conjunctiva was clear, but there seemed to be some thickening, as the palpebral slit was slightly narrower than that of the opposite eye and the patient was not able to open the affected eye quite as widely as the right. The lung condition and throat disease were quiescent during the treatment and have not since been affected by the reactions. The patient is now doing light office work for the first time in two years.

Study of an Unusual Glycosuria.—A case of glycosuria with apparently lowered renal threshold for glucose is reported by Langstroth. There were no other symptoms of diabetes. There was evidence of abnormal carbohydrate metabolism.

Graham-Steel Murmur in Mitral Stenosis.—Thirty-six cases of mitral stenosis were studied by Goodman. These cases were definitely mitral stenosis and not aortic insufficiency, with a Flint murmur. Of the thirty-six cases, twenty-four were pure mitral stenosis, i. e., with no insufficiency, and twelve were associated with a definite systolic murmur of an insufficiency. In the thirty-six cases a diastolic murmur along the left border of the sternum was heard twelve times, or in 33.3 per cent. of the cases. In the twenty-four cases of pure stenosis it was heard nine times, or 37.5 per cent., and in the twelve cases of stenosis with insufficiency it was heard three times, or 25 per cent. It would seem, therefore, that the Graham-Steel murmur is heard rather more frequently in the pure cases than in those associated with insufficiency.

Influenza-Pneumonia Showing Gas in Fascial Tissues.—Twelve cases of this kind are reported by Clark and Synnott. Three cases ran an uneventful course and recovered without surgical procedure. At necropsy the gas-containing tissue showed little blood in the vessels. It presented no discoloration, no congestion, no induration or other signs of inflammation. Bacteria were not recovered. Gas was not found within the muscle sheaths. The distribution of the gas corresponds with what we would expect to be the dissemination of gas escaping from the weakened alveoli of the lung under pressure. The authors are of the opinion that the "gas" in the above cases of pneumonia is air from the lung which reaches its distribution as a result of purely mechanical factors. They do not believe the gas is of bacterial origin.

Renal Diabetes.—Bailey reports two cases. He believes that renal diabetes, or better, "renal glycuresis," should be considered broadly as a condition of glycuresis not dependent on a temporary increase of blood sugar in an individual free from symptoms of diabetes mellitus. The condition can be recognized by morning synchronous blood and urine sugar tests, the specimens being collected before the patient has had anything to eat or drink. At least two types can be recognized: (1) cases with normal or subnormal blood sugar and glycuresis, which is greatly influenced by blood sugar changes; (2) cases with a constant glycuresis which varies with the rate of urinary excretion and is little influenced by blood sugar changes.

Multiple Endothelioma of Skin.—The type of endothelial new growth seen by Wise in two cases is very rare. Clinically, tumors of endothelial origin may be indistinguishable from the efflorescences of urticaria pigmentosa, xanthoma, soft moles, syringocystadenoma, multiple benign cystic epithelioma and perhaps other dermatoses. The study of sections occasionally reveals new growths of endothelial origin.

Transfusions of Citrated Blood.—The 200 transfusions of citrated blood made by Lewisohn were done for the following reasons: (*a*) hemophilia and allied conditions, 14 cases, 15 transfusions; 11 cures, 3 deaths; (*b*) purpura hemorrhagica, 16 cases, 20 transfusions; 4 cures, 5 improved, 2 results unknown, 5 deaths; (*c*) gastro-intestinal hemorrhage, 11 cases, 20 transfusions; 2 cures, 1 improved, 8 deaths; (*d*) cholemia, 5 cases, 11 transfusions; 5 deaths; (*e*) postoperative hemorrhages, 13 cases, 16 transfusions; 6 cures, 7 deaths; (*f*) hemorrhages from the female genital organs, 2 cases, 2 transfusion; 2 deaths; (*g*) traumatic hemorrhages, 2 cases, 3 transfusion; 1 cure, 1 death; (*h*) pernicious anemia and leukemia, 24 cases, 39 transfusions; 7 improved, 4 not improved, 13 deaths; (*i*) primary and secondary anemia, 4 cases, 7 transfusions; 3 cures, 1 improved; (*j*) preoperative and postoperative transfusions, 35 cases, 39 transfusions; 12 cures, 23 deaths; (*k*) sepsis, 5 cases, 7 transfusions, 5 deaths; (*l*) incurable conditions (transfusions performed at request of family) 12 cases, 12 transfusions; 12 deaths; (*m*) general debility, 6 cases, 8 transfusions; 1 improved, 1 result unknown, 4 deaths; (*n*) acute poisoning, 1 case, 1 transfusion, 1 cure.

Effect of Fatigue on Cardiac Irritability.—The evidence obtained by Mendenhall from his experimental work leads him to believe that the heart, like other tissues of the body, is affected by the products of fatigue. Extreme fatigue, i. e., carried to a point impossible of attainment by voluntary efforts, causes a depression of the electrical irritability of the heart, followed by a rise in irritability which may continue for some time. Moderate fatigue, i. e., carried to a point possible of attainment by voluntary efforts, causes a marked rise in the irritability of the heart muscle.

Output of Epinephrin in Shock.—The rate of output of epinephrin in dogs and cats, after the blood pressure had been permanently lowered by exposure and manipulation of the intestines, by partial occlusion of the inferior vena cava, by hemorrhage and by "peptone" injection, Stewart and Rogoff found to be the same as before the lowering of the blood pressure, within the limits of error of the methods used for assaying the epinephrin. A marked increase in the rate of output of epinephrin was produced by strychnin.

Influence of Organ Extracts on Gastric Secretion.—Rogers and his associates found that a slightly alkaline saline solution, or alcohol, extracts from the thyroid some noncoagulable material which is a vigorous stimulant for the gastric secretion. This material produces its effects at least in part by intensification of the functions performed by the terminal filaments of the (gastric) vagus. Extracts similarly made from the pathologic tissue of the adenomatous or hyperthyroid human glands are inert. Extracts of the suprarenal gland vigorously inhibit gastric secretion. These extracts all contain more or less epinephrin and, therefore, it is presumable that their effect is produced by intensification of the inhibitory function which is ascribed to the (gastric) sympathetic. Epinephrin is not as active a gastric inhibitor as suprarenal proteins obtained from extracts of the whole gland. These suprarenal nucleoproteins contain only traces of epinephrin. Extracts of the pituitary gland also inhibit gastric secretion, but only about one half as vigorously as do extracts of the suprarenal.

Treatment of Hemorrhage by Gum Solutions.—In the experimental work done by Penfield, the blood pressure of experimental animals was kept at a shock level for various lengths of time by progressive bleeding so that their condition resembled that which must frequently exist in wounded men at the front who have sustained severe and continued loss of blood. After analyzing the condition of these experimental animals according to the duration of low blood pressure, the amount of blood lost and the degree of acidosis resulting, Penfield was not able to show that gum-sodium bicarbonate solution or gum-glucose solution is more efficacious in saving life than is an isotonic solution of sodium chlorid. By perfusing an isolated vascular bed it was shown that following a large hemorrhage there is a primary constriction of the peripheral vessels. With continued low blood pressure this constriction passes off and dilatation supervenes. Associated with this dilatation the venous pressure rises while the arterial pressure is falling. All dogs in which the venous pressure rose while the arterial pressure was falling for a period of twenty minutes or more, died regardless of treatment. The effects of stimulation of the saphenous nerve while these animals were in a condition of profound shock indicated that the reflexes affecting respiration and blood pressure were not paralyzed.

Springs of a Nation's Life.—Abstracted in The Journal, Dec. 28, 1918, p. 2172.

Influenza in Relation to Pregnancy and Labor.—According to Bland's observations, epidemic influenza, of a mild and moderate character, occurring in pregnant women, is not associated with grave danger to the mother or her gestation. Influenza, when severe and associated with pulmonary complications, is an extremely serious affection and is associated with abortion or premature labor in a large percentage of cases, frequently followed by death of both mother and child. The disease in the mother is distinctly a contact infection.

Cesarean Sections.—In Beck's series of thirty-seven cases only one mother died; death was due to eclampsia.

Cure of Prolapse of Uterus.—The Sims-Emmett-Baldwin combined procedure has been used by Judd for five years with uniformly good results.

Influence of Influenza on Gynecologic and Obstetric Conditions.—A review of the literature by Farrar disclosed that mild attacks of influenza have no influence on gynecologic or obstetric conditions. Severe attacks produce menorrhagia and exacerbation of chronic gynecologic conditions, and often abortion, premature delivery, or stillbirth. Labor is prolonged and tedious. Pregnancy has an unfavorable influence on the course of a bronchitis or pneumonia influenza. Induction of labor has no beneficial effect on the course of influenza. The chances of general infection are greater if influenza occurs during the puerperium.

Influenzal Pneumonia in Pregnancy.—Kosmak does not agree with others in the belief that pregnant women are more liable to contract influenzal pneumonia than the nonpregnant.

Influenza Complicating Late Pregnancy.—According to Welz, the prognosis for women suffering from influenza in late pregnancy or labor is good, providing there is no pulmonary complication. A small percentage have premature labor with a considerable number of stillbirths. Those suffering the complications of lobar pneumonia or bronchopneumonia are desperately ill. If the case be mild with slight symptoms of toxemia the result may be favorable. The severe type is almost invariably fatal. Cyanosis, air hunger, leukopenia and low blood pressure are unfavorable signs. A change from leukopenia to leukocytosis signifies a favorable reaction. An increase of systolic and especially diastolic pressure is a hopeful sign. Increasing cyanosis and air hunger indicate a rapidly fatal termination.

The severe cases of pneumonia in late pregnancy suffer from a severe toxemia. The fate of the fetus is linked with that of the mother. An effort to save one, disregarding that of the other is apt to be disastrous to both. Hope for both lies in overcoming the toxemia and not in induced labor or forced delivery. It is the toxic state which is fatal, not the delivery, though this is an added strain on the mother. So efforts to hurry delivery are more harmful than noninterference. Just as in eclampsia, the best results will come from efforts to control the toxemia. The chances for the fetus are bad. The toxic state either causes antenatal death or premature labor which is apt to be fatal to the fetus. The fetal mortality is lessened where the mother recovers. There it is inadvisable to make efforts to save a morbid child by means which are detrimental to maternal life. All efforts should be made to control the toxic state early in the disease. The best hopes for both mother and child lie not in meddlesome obstetrics but in overcoming the toxemia.

Treatment of Sepsis.—Behan's article may be summarized as follows: Sodium carbonate or bicarbonate has a definite place in the treatment of infections. It seems in early stages of sepsis, including pneumonia, to be almost specific. In the later stages of pneumonia and of sepsis, injection is apparently contraindicated. In the early stages of infection the intravenous method of injection is the best. Glucose solution, if used in the later stages of pneumonia, should be used alone because the exhibition of the alkali reduces the coagulability of the blood to such a degree that it causes a tendency to pulmonary edema. If the glucose solution is to be used in the early stages of pneumonia it may, because of the increased viscidity of the blood, hinder the exudation. Salvarsan is also of value, especially in septicemia. Vaccines are of value in certain cases and in all obstinate infections should be exhibited. Vaccines in overdose seem to have a deleterious influence. Antistreptococcic serum is of great value in streptococcic infection. It, however, should not be given on a falling temperature and if the temperature remains stationary it should be given only in greatly reduced doses. A chill following its administration is not a bad omen. It should never be mixed with any foreign material. Large initial doses should be given, however, in all cases; small preliminary injections should be given as a test for serum sickness. Transfusions of blood are of distinct value in sepsis, especially in those cases of falling blood pressure.

Transfusion Reactions.—No method of transfusion is reaction-free, and the reactions have been ascribed to a variety of causes, but without effort at experimental analysis. Drinker's and Brittingham's experience with transfusion by the citrate method gives a larger number of reactions than are reported elsewhere. Out of eighty-three transfusions they have had a rise in temperature of 2.5 degrees fifty times, or 60 per cent., and of this number thirty-nine, or 47 per cent., have had chills. These figures include all the transfusions of whole citrated blood which have been done by different individuals at the Brigham Hospital. In order to test the matter further they have done seventeen such transfusions, using the most extreme care in the effort to reduce the reaction percentage. In these transfusions there were nine rises in temperatures above 2.5 degrees, or 53.3 per cent., and seven chills, or 40 per cent. Removal of the plates and a comparable number of white cells by defibrination, with thorough washing and suspension of the red cells in similar saline solution has resulted in 20 per cent. of reactions in fifteen transfusions. Addition of citrate from one to two hours before injection to transfusing blood so prepared has resulted in 44 per cent. of reactions in nine transfusions.

While the totals of the different types of transfusions which have been employed are not large, it appears that three elements make up the final total of reactions in citrate transfusion: (*a*) very rare gross incompatibilities, which escape in vitro detection (*b*) changes in the plates, part of the process of coagulation; (*c*) direct action of the sodium citrate on red cells promoting hemolysis.

Cardiac Arrhythmias.—Barker and Richardson record a case in which remarkable disturbances of cardiac rhythm were encountered in association with (1) peridental, maxillary and tonsillar infection, and (2) minute adenomata of the thyroid gland; and in which marked improvement followed treatment of the infected foci and partial thyroidectomy. There were observed in this patient at one time or another the following: (1) physiologic rhythm; (2) dislocation of the pacemaker from the sino-atrial node to points elsewhere in the atrium; (3) alternate atrial extrasystoles; none of which provokes a ventricular response; (4) alternate atrial extrasystoles, many of which provoke a ventricular response; (5) paroxysmal tachycardia and atrial flutter.

Pituitary Headaches.—A disproportion between the pituitary body and the sella produces pressure on the sensory nerves to the dura; and by its encroachment on the cavernous sinuses it may cause interference with the cerebral circulation, the whole setting up the train of pituitary symptoms, including headache. Pardee describes pituitary headache as having three characteristics: its location; its duration and persistence, and its relief under specific medication. The headache is situated "deep in the forehead behind the eyes." Deep pressure on the temples may elicit some tenderness. This headache is very persistent, usually lasting from one-half hour to forty-eight hours, and it may be continuous, frequently coming on in the female at the time of the menses. It often leaves very suddenly, returning again with exacerbations; it is accentuated by excitement, stooping over, and by the ingestion of sugar. At the climax of the headache there may be nausea and vomiting, with which there will come relief. Marked fatigue accompanies the headache, the patient hardly being able to drag himself about, and there is present to stroking a broad white skin line as evidence of suprarenal deficiency caused by the drain on the suprarenal function by the exhausted pituitary. The patients feel slowed down in their activity, yawn excessively, are sluggish and willing at any moment to seek an opportunity for sleep. These patients are particularly prone to attacks of depression, which come on without any cause, and have as their basis some very insignificant fact.

Knowing that the pituitary, together with the suprarenals, controls the mobilization of sugar in the body, it is not strange that these patients should have anomaly of sugar metabolism, as is seen in the periodic development of an intense craving for sweets, a sort of dipsomania, as it were, for sugar. The satisfaction of this desire being completed by eating candy, it is almost invariably followed by a typical pituitary headache. Owing to the increased demand on it, there is an enlargement of the pituitary gland, and following on this the suprarenals are called on to assist in mobilizing the sugar, the excessive drain on them causing great fatigue and the formation of a vicious circle. The administration of whole pituitary is a specific, ¼ to 2 grains three times a day; an average for an adult is 1 grain, preferably given one hour after meals. Continuous medication with pituitary will result within a few days in a decrease in the intensity of the headaches; there will be a longer period between their occurrence, the head will feel less "tight," and fatigue, nausea, and vomiting will also disappear.

Etiology of Cholecystitis.—By making cultures of the emulsified tissues of gallbladders or adjacent lymph glands, streptococci were found by Brown to be the chief microorganisms associated with cholecystitis. The direct etiologic relationship of the streptococcus is established by their presence, often in numbers proportionate to the degree of gross and microscopic changes, by their having elective affinity for the gallbladder of animals and by the specific agglutinating power of the serum of the patient from whom isolated. The elective affinity for the gallbladder of animals of the strains from the tonsils indicates strongly that cholecystitis is commonly a blood borne infection from a focal source.

Physiologic Action of Cantharis.—From their investigation Morgulis and Muirhead conclude that cantharis is not a drug which may be used experimentally to induce polycythemia, inasmuch as it does not cause a production of new red cells, but merely occasions a condensation of the blood through the loss of water in the process of elimination of cantharis by the kidneys.

Hydrocephalus and Choked Disk in Dogs.—Kornder summarizes the results of his experiments as follows: The production of hydrocephalus in dogs is accompanied by a distended optic sheath, hemorrhages and engorgement of the retinal veins and an edematous swelling of the nerve head, thus presenting features which characterize choked disk in man. This introduction of fluid under tension into the subdural space will also produce a like picture. The introduction of fluid under tension into the subdural spaces in a dog that is thoroughly atropinized will lead to nothing further than just the congestive features of choked disk, and this only after a long period of sustained high intracranial pressure. A venous stasis produced by ligation of the external jugular is insufficient to cause any optic disk changes. The production of choked disk in cases of hydrocephalus is not dependent on the presence of inflammatory factors but arises mechanically as a result of high venous pressure and an obstructed lymph drainage, both caused by the primary factor, the increased intracranial pressure.

Vaccine Treatment of Bronchial Asthma.—Twenty-eight patients with bronchial asthma were treated by Walker with vaccines of the bacteria to which they were sensitive; 75 per cent. were relieved of asthma, and 21 per cent. were improved. Seventy-five nonsensitive patients were treated with vaccines made from culturing their sputum on plain agar; the predominating organism was usually the one selected for treatment; 46.6 per cent. were relieved of asthma and 16 per cent. were improved. Twenty-four nonsensitive patients were treated with vaccines made from culturing their sputum in dextrose bouillon and using only the streptococci; 37.5 per cent. were relieved of asthma and 25 per cent. were improved. Thirty-five nonsensitive patients were treated with vaccines made from culturing the sputum both ways; in other words, many types of vaccines were used; 31.4 per cent. were relieved and 23 per cent. were improved. Sixteen nonsensitive summer asthmatics were treated with vaccines, 31.2 per cent. were relieved and 25 per cent. were improved. Therefore, of 150 nonsensitive asthmatics who were treated with vaccines, 40 per cent. were relieved and 20 per cent. were improved. With the sensitive cases, the age of onset of asthma, the duration of asthma and the age of the patient when treated had little to do with the prognosis; however, with the nonsensitive cases these facts had much bearing on the prognosis; the older the patient is when asthma begins and the older he is when treatment is begun, the more unfavorable the prognosis from vaccines in nonsensitive cases. The permanency of relief from vaccines in the nonsensitive cases depends on the individual's resistance to the bacteria in question; therefore, the duration of relief from asthma varies.

*Subcutaneous Rupture of Spleen. I. J. Walker, Boston.—p. 211.
Influenza. J. Speares, Dublin, Ireland.—p. 212.

Acute Changes in Cells of Solar Plexus in Intestinal Conditions.—Two cases of insane patients are cited by Myerson in which acute intestinal conditions were associated with acute changes of the nerve cells of the type described as acute Nissl degeneration. A dementia praecox patient, woman of middle age, dying of volvulus, showed acute axonal reaction in the sympathetic cells of the solar plexus, without corresponding changes elsewhere. A juvenile paretic, dying of pleurisy with effusion of tubercular origin, fecal impaction and congestion of peritoneal blood vessels, showed acute axonal reaction in the sympathetic cells of the solar plexus.

Subcutaneous Rupture of Spleen.—Walker's patient was kicked by a horse in the upper abdomen, but continued to work, loading and unloading coal wagon until noon when a fellow workman told him to stop as he did not look well. His only complaint was a slight pain in the abdomen. The patient walked to a doctor's office. The doctor gave him codein for what appeared to be a slight diaphragmatic pleurisy. There was nothing further found on examination except slight tenderness over the left upper abdomen. The pulse, temperature and respiration were normal and remained so during the next few days. On the third day the patient, without permission, sat up to eat his dinner. About noon the next day the patient suddenly felt "something give way" in the upper abdomen. He went into a state of collapse. There was marked pallor and thirst. The abdomen was considerably distended, with rigidity and spasm on the left side, especially in the upper half. There was also shifting dulness in the flanks. Under ether, the abdomen was opened through a high left rectus incision. There was at once an escape of large amounts of old and fresh blood. Quick exploration revealed a ruptured spleen which was bleeding profusely. Splenectomy was done. At the end of the operation the patient's condition was poor. Salt solution was given intravenously and the patient stimulated. He refused to allow transfusion. He died two days later. Examination of the spleen after removal showed the capsule loosened from the surface as if it had been lifted by a slow extravasation of blood from beneath. The peritoneal covering, capsule and spleen itself were torn through the middle, in a line running from the hilus backward to the posterior aspect, practically dividing the organ into two pieces.

Nutmeg in Treatment of Amebic Dysentery.—A dysentery patient who had resisted treatment with emetin was placed by Leidy on 30 grains of selected grated nutmeg three times a day, care being taken to obtain a pure extract. The effect of treatment on the subjective symptoms was decided and prompt; the frequent spasmodic (colitic) pain disappeared; three days later, examination of stools showed fewer cysts, with abatement of *Trichomonas intestinalis* infection. At the expiration of seven days very few cysts were found; the patient has shown steady improvement in his physical condition. Three weeks after treatment no cysts were found. Regular examination of the stools for the past four months, by the ether centrifuge method, has been negative, as to both the vegetative and the cystic forms.

Nonsurgical Treatment of Exophthalmic Goiter.—The treatment used by Bram in the cases cited was hygienic, dietetic, medicinal, electrical and hydropathic. He insists that in the treatment of exophthalmic goiter, individualization is of inestimable importance. Rest, physical and mental, must characterize all treatment instituted in this disease. The maintenance of the digestive functions in as normal a condition as possible is of vital importance. In every case Bram gives quinin hydrobromate, 4 or 5 grains, three times a day, combined with an appropriate hematinic and a harmless sedative. He believes that such a mixture acts in a specific fashion, all things being equal.

Vaccine Treatment of Whooping Cough.—A further experience has confirmed Luttinger's belief that pertussis vaccine, when given in high doses and at the proper intervals is the best remedy for the prevention and cure of whooping cough. With the exception of very severe cases these patients received no other treatment but the vaccine. The usual hygienic precautions regarding fresh air and the regulation of feeding are taken. The doses are as follows for a child 1 year old: half a billion, 1 billion, 2 billion, 4 billion, 8 billion and 16 billion. The injections are given subcutaneously with an ordinary hypodermic syringe, every other day, an interval of five days being allowed between the third and fourth dose for recuperation. For prophylaxis, the first three doses are sufficient.

Nocturnal Enuresis in Adults.—The ages of the sixteen soldiers whose cases are cited by Allis ranged from 19 to 31 years. The treatment employed was varied to suit individual cases. As they were all consistently wetting their beds from one to three times a night they were awakened at intervals of about two hours, the time being lengthened as individuals showed improvement. Bowels and diet were carefully looked after. The most important part of the treatment, Allis believes, was the local application through the endoscope of varying strengths of nitrate of silver solution 1 to 5 per cent., varied at times with deep instillations of 2 or 3 drops of the same solution, or anterior irrigations of the urethra with a solution of silver one to 3,000 or 5,000. These treatments were given at intervals of about four or five days. In a few of the cases Allis gave belladonna and ergot internally in small doses, but apparently it did not help much.

Sodium Morrhuate in Tuberculosis.—By a similar process to that by which sodium gynocardate is made from chaulmoogra oil, a preparation has been made of the sodium salts of the unsaturated fatty acids of cod liver oil after extraction by ether. Rogers has termed this preparation "sodium morrhuate." A 3 per cent. watery solution is sterilized in an autoclave and 0.5 per cent. phenol is added. This may be injected subcutaneously with very little pain, and also intravenously. Its subcutaneous injection is nearly painless, and a year's experience has shown it to be of great value in leprosy. Rogers regards this as being a most important point, as it proves that there is nothing absolutely specific in the products of chaulmoogra oil in that disease, and supports his view that the sodium salts of the unsaturated fatty acids of these two oils act in some way on the coating of the acid fast bacilli, that of tuberculosis having been shown to contain palmitic and other unsaturated fatty acids.

During the past year sodium morrhuate has been used with very promising results in tuberculosis by several careful observers, and morphologic changes have been noted in the tubercle bacilli in the sputum. Rogers usually begins with 0.5 c.c. of the 3 per cent. solution, and increases it by 2 to 4 minims at each injection, which may be given two or three times a week until a reaction occurs; then a week's interval is left and the dose reduced. The injections are given subcutaneously until they reach an inconvenient size, such as 2 c.c., when intravenous injections can be begun with 0.5 c.c., gradually increased in the same way as with the subcutaneous ones. Improvement of phthisical cases is seen in reduction and cessation of fever, diminution of expectoration and cough, and steady gain in weight: the tubercle bacilli in the sputum greatly decrease in numbers, and may in time disappear. Moreover, they commonly show deficient acid staining and a granular or beaded appearance, indicating that they are actually being destroyed within the tissues.

Improved Methods of Infant Feeding.—Laing urges greater quantities of food, and shorter intervals of feeding, depending on the size of the child, and its digestive powers.

Treatment of Early Syphilis.—Gibson uses mercury, arsenic compounds and potassium iodid. He says that mercury alone can cure many cases of syphilis if persisted in for a sufficiently long time, but it is questionable if a course of less than two years is of any value at any stage of the disease. With arsphenamin and its alternatives, however, the term of active treatment can be shortened greatly, and in the very early stages of the infection the disease can be aborted, although it may be advisable to keep the patient under observation for two years. Gibson believes that a positive reaction is indicative of syphilis in its secondary stage, and the disappearence of the positive reaction for six months after treatment with mercury has been discontinued is evidence of cure. He has not seen a case of secondary syphilis—which has not had any treatment—give a negative reaction; nor has he seen a case of secondary syphilis which gave a negative reaction for six months after treatment with mercury and arsphenamin was discontinued again develop a positive blood test, unless reinfected.

Proflavine Oleate in Treatment of Wounds.—Berkeley and Bonney draw attention to the value of proflavine oleate in the treatment of certain war wounds, notably those in which an exceeding tender raw surface of considerable extent exists, the dressing of which is productive of acute pain. Their method consists in either spreading a thick layer of the oleate ointment on a single thickness of white gauze and then applying it to the wound, or spreading the oleate direct on to the surface of the wound and then covering it with a single layer of gauze. This dressing does not need to be changed for several days, and, when it is removed, strips off from the sensitive surface without any dragging or pain. It is equally applicable to any large flat-surfaced wounds, such as those left after wholesale excision of the thigh or buttock muscles and so forth. The authors suggest that after all operations in which a flat raw surface is necessarily left, the wound should, from the first, be dressed with proflavine oleate, in the manner described.

Radium Treatment of Exophthalmic Goiter.—One of the conditions for which Turner has found radium consistently useful is exophthalmic goiter. He has treated upward of fifty cases, and with one exception all of those patients have derived more or less benefit. The exception was a woman of 22 years of age, who suffered from extreme nervousness, and who died of hyperthyroidism and toxic phenomena within a fortnight of the treatment. The benefit that patients with exophthalmic goiter derive from the expert application of radium is reflected in their general condition and in their special symptoms. They regain strength, lose the tired feeling and put on weight, and at the same time the tachycardia, tremor, and breathlessness are diminished and may disappear altogether. The thyroid gland becomes harder, denser, but usually does not diminish in size, and the exophthalmos is but little affected. Turner treats each lobe, and the isthmus of the thyroid, and the thymus. A dose of from 200 to 400 milligram hours, properly screened so as to avoid injury to the skin, may be given over each of these areas, and the patient may then be sent home for some three months, when more treatment may, if necessary, be given. As the skin over the front of the throat appears to be very sensitive to radium rays, great care should be taken to avoid over exposing it.

*Etiology of Sprue, Pellagra and Scurvy.—L. Nicholls.—p. 21.
Sprue Associated with Tetany. P. W. Bassett-Smith.—p. 24.

Etiology of Sprue, Pellagra and Scurvy.—According to Nicholls, most of the circumstances connected with sprue support the view that it is caused by the infection of a microorganism, whereas, scurvy is more or less dependent for its appearance on a lack of some necessary constituents in the diet, previously consumed by the sufferers; in these respects, pellagra falls midway between these diseases, and for every suggestion that it is an infectious disease, a considerable opinion exists that its etiology is explained by the nature of the patient's antecedent diet. Nicholls thinks that no cases of these diseases will occur unless both factors are present to some extent, but it must be remembered that the deficiency in a diet may be greater or less; and the degree of pathogenicity of an organism and the resistance to it varies. The latter is the predominant factor in sprue, and the former in scurvy, but they are fairly evenly balanced in pellagra.

Hilus Tuberculosis in Adult.—The term hilus tuberculosis in the adult as used by Riviere refers to a fresh and active process, involving the deep areas of the lungs where remain the old foci of childhood infection, and thence spreading outward toward the surface. It thus stands in close relationship to the common form of tuberculosis of childhood, though with less tendency to glandular involvement; and also in decided contrast to apical phthisis of adults, a localized infiltration involving the apex of the lung. Hilus tuberculosis is commonly a peribronchial disease of chronic and intermittent course. Such symptoms as are of toxic origin are identical for hilus tuberculosis and apical phthisis. In addition, certain symptoms occur which may be considered more characteristic of hilus tuberculosis than of apical phthisis. Particularly, shortness of breath on exertion is a symptom which is often prominent, and due in some cases to widespread peribronchial disease and in some to the emphysema and bronchitis which are occasional complications. Chest pain is also fairly common, often in the central regions of the chest, occasionally in the side in association with the marginal pleurisies which are such frequent accompaniments of this disease. Most important of all as evidence of deep disease is a bilateral narrowing of "Krönig's isthmus" of apical resonance at the top of the shoulder. The whole clinical history of the affection is discussed in detail by Riviere.

Substitution of Air for Oxygen in Anesthesia.—During a temporary failure in the supply of oxygen for anesthetic purposes, Fryer tried ordinary air in place of oxygen with the Hewitt apparatus. This proved so satisfactory that he has entirely discontinued the use of gas and oxygen, and some hundreds of administrations of duration varying from a few minutes to a full hour have been given by the air method. No ill effects have been noticed during or after administration, and there has not occurred any instance of postanesthetic vomiting. The limitations of this method are much the same as those of gas and oxygen, though it is easier to produce and maintain a satisfactory degree of muscular relaxation when using air. It is very easy to administer in cases where vitality has been reduced by shock, hemorrhage, or sepsis, while strong, full-blooded men are difficult subjects. Fryer has not so far used the method for intra-abdominal operations, and for intrathoracic he prefers oxygen bubbled through chloroform and warmed by the Shipway apparatus; but for amputations and most general surgical procedures it is well adapted unless postural requirements contraindicate by rendering it difficult to maintain the facepiece in position. This method has advantage over gas and oxygen from the points of view of economy and portability of apparatus.

Staining Diphtheria Bacillus with Toluidin Blue Mixture.—The staining solution which Sutherland has used for eight years has the following composition: toluidin blue, 0.1 gm.; glacial acetic acid, 0.5 c.c.; distilled water, 100 c.c. The smears are made on slides and are fixed with heat in the usual way. When large numbers of cultures have to be examined it is most convenient to make the smears in a series of ten or twelve at one time. A drop of the stain is placed on each film and a coverglass is then placed over the preparation. The excess of stain is removed by blotting each slide between two layers of blotting paper immediately before being examined. The first slide is ready for examination about one minute after the stain is applied, and the others are taken in rotation. The best results are obtained by using strong artificial light. When slides are stained in this way the polar granules of *B. diphtheriae* are of a deep reddish purple, while the bodies of the bacilli appear faintly blue. Most of the organisms found in diphtheria swabs, including Hofmann's bacillus, are more faintly stained, so that *B. diphtheriae* is readily detected when present only in small numbers. The stain may also be used in a similar manner for demonstrating the bacillus in smears made direct from the swabs, in which case the film should be allowed to stand in the stain for from two to three minutes before removing the excess.

Causes of Kidney Pain and Treatment.—Harris cites cases of stricture of the ureter, renal tumor, obstruction of ureter at ureteroplevic junction by aberrant vessels, fascial bands, etc., ureteral obstructions from tumors in the abdomen and pelvis (e. g., uterine fibroids, cancer of the cervix uteri, etc.); certain bladder lesions, e. g., benign and malignant growths, diverticula, etc.; seminal vesiculitis; inflammatory conditions of the broad ligaments and of the appendix; obstruction of the urethra by syricture, prostatic hypertrophy, median bar formation as causing kidney pain. The treatment in each instance is outlined.

Prostatectomy.—The procedure which McKillop has employed in three cases is said to render the operation safer and more rapid of accomplishment. The space of Retzius is exposed through an abdominal incision. A gauze sponge in keeping with the size of this space is tightly packed in position, so as to push the bladder well down toward the perineum. The usual curved transverse incision is next made across the perineum and deepened until the perineal muscles are met with. The plane of cleavage between the rectum and the bulb is sought for and opened up. The prostate gland will be found lying low in a most accessible position. The dissection is further deepened until the false capsule is exposed; it must be continued externally to that structure. Counter pressure is made over the hypogastric swab until the prostate is pushed down almost flush with the perineum when the subsequent steps are carried out under the guidance of the eye. The bleeding, which in these cases is usually a source of much danger, can be controlled with the greatest ease. The puboprostatic and the lateral true ligaments of the bladder are cut through, and with a little care the finger is hooked over the pelvic fascial capsule and the gland separated from the base of the bladder external to the internal sphincter. When further separation is impossible the bladder wall is cut through in a circular manner. The vasa deferentia and the membranous urethra, with its contained catheter, are then completely divided and the prostatic capsule and its gland removed in toto. A fresh, large-sized catheter is passed down the urethra, to replace the divided one. The new catheter is guided into the bladder. All bleeding points are very carefully caught and ligated, and the redundant portion of the bladder wound closed with catgut, care being taken to avoid catching up the bladder mucosa. A gauze drain in a split tube is introduced down to the base of the bladder. Iodoform gauze is packed firmly about this, and the lateral portion of the transverse perineal wound united by silkworm-gut sutures. The gauze packing in the perineal wound is taken out and replaced in forty-eight hours, and the tube is removed on the fourth day. The indwelling catheter is changed daily after the first week, and sounds are susequently passed.

Vaccine Therapy of Influenza in Dunedin.—It is claimed by Champtaloup and Drennan that inoculation with a vaccine composed of the chief causative organisms may or may not protect against infection. The length of the immunity conferred is doubtful. It is probably short. To effect a cure the vaccine is practically proved to be of extreme value in controlling the disease and limiting complications. The first dose (80 to 100 millions of mixed vaccine) is given as soon as possible, 400 millions seven days later, and another dose three days later, if all goes well. In severe cases larger doses are given intravenously. For the rest, the treatment is symptomatic.

The Blood in Influenza.—Maestrini refers to the blood during influenzal bronchopneumonia. The serum seemed to have completely lost the faculty of precipitating colloidal silver. In influenza without pneumonia the blood behaves like normal blood in this respect. It is possible that the electric charge is responsible, as colloidal silver has a negative electric charge. It is precipitated by normal human serum, adding 20 or 30 drops of the serum to 10 c.c. of a 1:500 aqueous solution of the silver salt.

Tuberculous Pericarditis.—Cardarelli based his diagnosis in the case described on the enlargement of the liver and tracheobronchial glands, the cyanosis and the edema in the legs. These features of the case testified to impeded return of the venous blood to the heart. There was no murmur or effusion, and the rhythm was normal, consequently this seemed to exclude all forms of heart disease except adhesion of the sheets of the pericardium. This explained the extreme enlargement of the liver but there was no history of rheumatism in the case. The enlarged tracheobronchial, axillary and inguinal glands and bilateral pleurisy with effusion stamped the heart disease as probably tuberculous, although the tuberculin test was negative and there was no fever or loss of flesh. The lymphatics provide an easy path for spread of a tuberculous pleural infection to the pericardium. It has been his experience that in these cases of adherent pericarditis the heart displays a tendency to shrivel when the trouble is of tuberculous origin, while it tends to become hypertrophied when due to rheumatism. The latter injures the valves and sets up a further vicious circle, all of which is lacking in the tuberculous form. In the case described he gave no heart tonic but only purgatives and diuretics. This reduced the blood pressure, greatly relieving the patient, the cyanosis subsiding almost completely, and the condition keeping fairly good under repose and a light diet, but a cure cannot be anticipated.

Vitalization of Artificial Limbs.—Pellegrini now has a record of twenty-seven plastic motor operations, and he has compiled seventy-eight others from Italian literature. His own primary cinematic amputations include one "key" plastic motor operation, twenty "loop" operations and one with "key" plus "loop." In three cases the outcome was not satisfactory, but in all the others the cinematization was a success. The lifting power of the motors thus provided ranged from 15 kg. cm. to 50 kg. cm., and is still increasing so that 100 kg. cm. is anticipated in the near future. His experience teaches the advantages of a "loop" over a "key"; of lateral rather than terminal motors; of alternating instead of single motors, and the superiority of skin bridge flaps over pedunculated flaps.

*Malignant Tumor in Child Kidney: Three Cases. F. Rossi.—p. 617.

Malignant Tumors of the Child Kidney.—Rossi reviews the literature on this subject and reports three cases. There are recur- only a few instances of operative cures on record and rence is frequent, but an operation is the only means of possible relief and the success in one of his cases justifies high hopes with radical intervention. In one of the cases on record the tumor compressed the ureter from the other kidney, inducing hydronephrosis in this, and the urine from the sound kidney found its outlet through the sarcomatous kidney, the ureter from this being still permeable. Enlarge- ment of the kidney is always the first symptom of the malig- nant disease in children. Hematuria is not always present, and pain is an unreliable element in the differential diagnosis. His first two cases were in children of 2; one was inoperable, but the other child recovered and seems still in perfect health, eight years since the nephrectomy. The tumor was a round cell sarcoma, weighing 600 gm. The child had been apparently healthy until two months before the operation. He removed the tumor likewise in the third patient, a girl of 8, and the child seems well but the interval since has been too short for the ultimate outcome to be known. In deciding whether the tumor was in the kidney or spleen he found instructive the appearance of a zone of resonance in front of the tumor when the intestine was inflated. This resonance is not encountered with a tumor in the spleen. A tumor in the intestine or mesentery generally runs a very rapid course, entailing cachexia early. Such tumors also are extremely movable while a tumor in the pancreas is not movable. A conglomerate of tuberculous glands might prove misleading, but almost invariably tumefied glands or other symptoms elsewhere would give the clue. A congenital cystic kidney may also simulate a malignant tumor. In a case of this kind, a hard elastic tumor in the kidney region, movable with respiration but without fremitus or resonance in front, without eosinophilia, the blood pictures and urine normal, was shown by exploratory puncture to be a cystic tumor implanted on the large right kidney. The left kidney was missing. Smooth recovery followed excision of the tumor.

Tumori, Rome

*Diet to Promote Retrogression of Tumors. E. Centanni.—p. 153.
*Myomatous Tumors of Stomach. F. Nassetti.—p. 172. Conc'n.

Dietetic Treatment of Cancer.—Centanni's article was summarized in The Journal, Oct. 26, 1918, p. 1446, when published elsewhere. As stated in the abstract then, he declares that the results realized by his experiments constitute the most definite that have been accomplished by modern cancer research to date. He reiterates further that there are always two factors involved in malignant disease, the special local anomaly, which imparts to the cells the capacity for tumultuous multiplication, and the lack of adequate defensive forces which normally would check any such tendency to unbridled proliferation. From this point of view, cancer may be classed as a constitutional disease. The constitutional defect is revealed by the inability to curb the tumor growth. In his dietetic experiments he aimed to suppress from the food or denature by excessive heating only those elements which promote growth. He removed the larger part of the tumor and then, under the dietetic restrictions, what was left of the tumor gradually atrophied instead of developing recurrence as otherwise would occur. As Ehrlich said, the fate of a tumor is determined by the differential of reciprocal nutritive avidity between the cells of the tumor and the other cells of the organism. This differential is extremely variable but, in any event, tonics and strengthening diets, especially milk, act in malignant disease like throwing oil on the fire. The human organism is peculiarly susceptible to dietetic deficiencies, and this promises well for dietetic influencing of cancers, especially when supplemented with other growth-depressing agencies.

Myoma of the Stomach.—Nassetti found among 140 myomatous gastric tumors on record, 58 simple myomas and 37 fibromyomas, 6 adenomyomas and 1 myxomyoma. All the others were of a mixed sarcomatous nature except 9 listed as malignant myoma. The clinical and histologic findings in each group are reviewed, with twelve plates of illustrations. Operative treatment is the only rational measure; in 40 operative cases tabulated from the literature the tumor was in the submucosa in 8 of the cases. One death is recorded in this group and in 9 in the subserosa cases. Pneumonia or embolism was responsible for at least 4 of these 10 fatalities. He gives colored plates of 2 large pedunculated myosarcomas growing from the outside of the stomach. Four pages of bibliography are appended.

*Spasm of Muscles of Orbit. J. M. Villaverde.—p. 317.
Milk as Vehicle for Iodin. A. S. Alvarez.—p. 322.
Ulceration from Vascular Lesions. Sicilia.—p. 325.

Influence of Influenza on Pulmonary Tuberculosis.—Triviño remarks that among the applicants at the dispensary in his charge there were last year 160 with pulmonary tuberculosis. Influenza had an unmistakably unfavorable action on many with "closed" tuberculosis, tubercle bacilli appearing in the sputum afterward. Chronic cases, however, did not seem to be influenced. An exceptionally large number of new patients with pulmonary tuberculosis are applying to the dispensary of late, all referring the onset of their disease to the period of epidemic influenza last spring. Most of them affirm that they were healthy until then.

Influenza.—Velasco reports two cases in which influenza deceptively simulated acute appendicitis. One of the patients died in forty-eight hours, the symptoms suggesting peritonitis. In several other cases there were absolutely no symptoms of influenza except moderate fever and delirium. Acute mania would have been the diagnosis if it had not been for the fever. In one lad of 17 the influenza passed through several phases, first a chill and severe intestinal hemorrhage, then a calm followed by symptoms of pneumonia, with subsidence of all symptoms the fifth day. Three days later the temperature ran up again, and the digestive apparatus was the storm center for two weeks. Then came a week of calm and normal temperature, and then a new phase of pneumonia, with final recovery. Calcium chlorid for the hemorrhage and diphtheria antitoxin were the main reliance in treatment, besides physical measures.

Radiologic Diagnosis of Duodenal Ulcer.—Carro regards as of diagnostic import the sagging of the pylorus, tenderness in the duodenal region, and increased gastric peristalsis. He has diagnosed a duodenal ulcer in many cases, confirmed later, in which there was nothing in the roentgen picture to suggest such a process. On the other hand, the roentgen rays have sometimes corrected his mistaken diagnosis of some affection other than duodenal ulcer.

Spasm of the Muscles of the Eyelids and Back of Neck.—Villaverde has been unable to find on record a case similar to the one he describes. An isolated spasm of the orbicularis palpebrarum compels the man of 59 to throw his head back in order to see, and the consequence of this is a spasm of the muscles of the back of the neck. The other muscles innervated by the facialis seem normal.

Clamps in Surgery.—Finochietto's long continued article has reached its sixty-first illustration of various modern devices for clamping, tying knots, crushing, etc.

Projectile in the Corona Radiata.—Solé noticed that the left arm did not show signs of paralysis until the twentieth day after the man had been shot from above in the right frontal region. There was no tendency to spasmodic contraction but the left leg dragged a little. The projectile was shown by the roentgen rays to be in the corona radiata, 2 or 3 cm. from the cortex, near the fissure of Sylvius. As the symptoms had been so long in developing and as they manifested a progressive course, the bullet was removed. It was reached through an incision in the cortex just above the fissure of Sylvius, close to the avascular edge of the circumvolution. The incision was 3 cm. long and 1 cm. deep and with a fine probe the bullet was located toward the center of the base of the brain, at a depth of 5 cm., by the resistance to the probe. There was not the expected click, as the bullet was found partly covered with adherent tissue. He did not attempt to suture the dura mater. The operation was done under local anesthesia and the patient answered questions without complaint of much discomfort. The previously lax monoplegia changed to spastic temporarily. There was no complaint of headache but vomiting kept up for three days. Then a change was made from fluid food to a thick tapioca dish and the vomiting stopped at once. The paralysis of the arm progressively subsided, the man being now able to raise his hand to his head and the strength returning to his arm, but the facial paralysis still persists.

Malignant Tumor in Mediastinum.—In Lopez' case the woman of 35, previously healthy, suddenly developed dyspnea and vascular disturbance with subdulness presternal and at the base of the right lung. The assumption of cancer was confirmed by necropsy within two months. The rapidly fatal lymphadenoma had not involved the other glands in the mediastinum.

Typhoidin in Diagnosis of Typhoid.—Mazza's experience with this reaction failed to demonstrate any diagnostic value for it.

The Brain with Senile Dementia.—Rojas reproduces the microscopic findings in brains with senile dementia.

Hexamethylenamin by the Vein in Typhoid.—Ymaz and Ayerza in this instalment of their article state that a physiologically isotonic solution is made of hexamethylenamin by dissolving it in a 4 per thousand salt solution. The preferable concentration seems to be a 30 per cent. solution in the 4 per thousand saline. If heated too much the solution becomes hemolytic, but this does not occur when heated merely to 70 C. for three hours in all, an hour at a time.

Repertorio de Medicina y Cirugia, Bogotá

December, 1918, **10**, No. 3

Influenza in Colombia. J. M. Montoya.—p. 113.
*Reconstruction of Urethra with Saphenous Vein. Z. C. Duran.—p. 116.
*Scarlet Fever at Bogotá. J. del C. Acosta.—p. 139.

Reconstruction of Urethra with Saphenous Vein.—Duran was impressed by the advantages of this plastic operation as successfully done by Legueu in 1916. Duran has applied the method himself in two cases, the success in one equalling that realized by Legueu. He has been unable to find any records of other successful operations of the kind, so he thinks that his case should rank as the second. The patient had several fistulas in the perineum, relics of urinary abscesses from stricture of gonorrheal origin. There was a gap of 1.5 cm. in the urethra after resection of the strictures. After dilating the stumps of the urethra and isolating these stumps, he resected a segment, 8 cm. long, in the saphenous vein in the triangle of Scarpa. This segment was then drawn over a bougie and placed in a jar with tepid Hayem artificial serum. Then it was implanted in a tunnel made out of the tissues of the perineum, drawing the skin up over it, instead of boring a tunnel with a trocar as Legueu does. In other respects he followed the latter's technic exactly. In his second case preexisting cystitis and fistulas, with enlarged prostate and incontinence, necessitated long preparation for the plastic operation, but it proved a complete success at last although supplementary urethrotomy had been required. It is the first time that a urethrotomy has been done on the urethra made from the saphenous vein. In this case the segment of vein was found narrower than expected, and it had to be well stretched before it could be used. There were also three anastomoses which had to be ligated when the 12 cm. segment was resected. In spite of these drawbacks, the reconstructed urethra is a complete success, no fistula being left, although the slight preexisting incontinence still persists.

Scarlet Fever in Bogotá.—Acosta warns that scarlet fever is becoming more common in Bogotá where it used to be very rare and appear in mild, incomplete forms. The cases seem to be growing more frequent and the type more severe. In dubious cases, the diagnosis is facilitated, he says, by the presence of bile pigment and Bence-Jones albumose in the urine. The albumose is abundant during the first two or three days but gradually disappears by the fifth or sixth day. It is a simple matter to determine its presence as it is precipitated by nitric acid, cold, and dissolves anew on heating. By pouring carefully the filtered urine on a little nitric acid, not allowing them to mix, the green ring characteristic of bile pigment forms and below it the yellowish white precipitate. The latter disappears on heating the tube but forms anew as it cools. Acosta does not know whether the albumose which he found constantly in scarlet fever occurs in other diseases. Strict isolation is imperative, and the easiest way to realize this is by sending the other children away from the home. The isolation should be kept up for five weeks after the febrile period; some say for seven weeks.

*Postinfluenzal Psychoses. E. F. Sanz.—p. 5.
*Acute Dilatation of Heart Consecutive to Trauma. U. Sarachaga.—p. 11.

Influenzal Psychoses.—Sanz' three patients with postinfluenzal psychoses were women between 22 and 34, inclined to nervousness or hyperemotionalism. The influenza was quite mild in two of the cases, lasting only three days. In one the psychosis was of the type of acute melancholia with suicidal tendency and refusal to eat. This patient had not recovered from excessive hemorrhages at a childbirth three months before. He ordered isolation and sedatives, giving a favorable prognosis. The cases demonstrate anew the importance of predisposing factors in such cases.

Acute Traumatic Dilatation of the Heart.—In the case described by Sarachaga the man of 40 fell from a height but was caught on a projection which he hit with his chest and hung suspended until rescued. The fright, contusion of the chest and the muscular effort of clinging to the support were followed by acute dilatation of the heart, with edema. Under digitalis the symptoms gradually subsided and by the seventeenth day normal conditions had apparently been restored. There have been no further signs of disturbance during the three months since to date. This complete recovery and the fact that the symptoms did not appear until forty-eight hours after the accident exclude a valvular lesion. The prognosis in such cases depends on the muscular force of the heart rather than on the degree of dilatation.

Alkalinity of the Blood.—Pando remarks that the alkalinity of the blood cannot be determined in the same way as with the other fluids of the organism because its red color masks the reaction in the change of tint. He discusses the various causes that may interfere with the reliability of the findings with various tests, and declares that the acidity of the distilled water used in the tests may have considerable bearing on the findings. Another source of error is the loss of alkalinity depending on the time the blood has been outside of the blood vessels, from the biochemical action of its diastases and enzymes. Distilled water always gives an acid reaction on account of the carbon dioxid present. The test method he describes in detail is based on the acidification of a given quantity of blood by means of a 200 normal solution of sulphuric acid in presence of neutral sodium citrate, estimating, by means of a 200 normal solution of sodium hydroxid, the excess of sulphuric acid which has not combined with the alkaline principles of the blood. He says that with a minute amount of blood this method is simple and easy although indirect.

Protection of Foundlings.—Paez gives a historical sketch of what has been done in the Argentine Republic to care for abandoned children. The first institution, the Casa de Expósitos, dates from 1779.

Sodium Hyposulphite in Respiratory Diseases.—Iarcho deplores the neglect of this drug which has been so highly commended by Huchard, Ayerza and others. He has used it himself on a large scale in the public hospital, and has been much impressed by its beneficial influence on cough and expectoration, and the improvement in the purulent sputum. He says that it is notoxic and has no by-effects except possibly a slightly laxative action in the sensitive. The usual dose is 2.5 or 3 gm. a day, or 1 gm. for children of 5. He gives it in hot, slightly sweetened, water. It is incompatible with acids, salts and especially the salts of lead, silver, mercury and iodin.

Sanitary Legislation in Peru.—Penna's article is the introduction to a book on the medicosocial bases of sanitary legislation in Peru, by Dr. Carlos Enrique Paz Soldan of Lima, director of the monthly, *Reforma Medica.*

Congenital Nephritis.—Dutrey and Widakovich report the case of a prematurely born child of a woman who had 1.50 gm. per thousand albumin in the urine. Delivery was spontaneous, but the placenta weighed 1,950 gm. while the child weighed only 1,700 gm. There was general edema of the cord and membranes and of the entire fetus. Lesions were found in the kidneys of the child indicating chronic nephritis, and this nephritis in the child evidently had cooperated in the production of the edema. There was nothing to suggest syphilis in mother or child. They know of only two other cases on record of congenital fetal nephritis, theirs being the third case to be published in accessible literature. In Sitzenfrei's case, the nephritis in the fetus was evidently acute.

Symphysiotomy Versus Pubiotomy.—Chamorro here concludes his long monograph on this subject, based on extensive clinical experience. He analyzes the advantages and disadvantages of each of these operations, his verdict being all in favor of symphysiotomy, for numerous reasons. The mishaps and their gravity are much less than with pubiotomy, and the puerperium is comparatively normal. There can be no clinical and surgical parallel between them, he reiterates. Symphysiotomy, done subcutaneously, may almost be called physiologic, as he shows by the case histories in full of thirty-nine cases in which one of these operations was performed at Buenos Aires, including eight personal cases. Considerable bibliography is appended, the list containing titles of forty-five articles or works on the subject that have been published in Argentina by thirty-one different writers.

Fibromatous Uterus with Foreign Body.—Diez removed the uterus on account of fibromatous changes and found an ordinary sewing needle embedded in the cervical tissue. The irritation from this may have been responsible for the extreme degree of fibromatous degeneration.

Prophylaxis of Leprosy.—Coni protests decidedly against the plan of segregating lepers on remote islands. It is far better, he argues, to have an accessible colony for lepers where they can see their friends and relatives occasionally. Agricultural colonies give them occupation and make their lot as bearable as possible. He appeals to the legislature to provide for compulsory declaration of leprosy. No census has ever been taken of the lepers in Argentina.

*Crasiology. C. Calleja.—p. 1013. Concluded in No. 3396, p. 22.

Historical Fees.—Sanz reviews the history of large fees, beginning with that paid by the king Antiochus, 300 B. C., to the physician Erasistratus of Alexandria. He is said to have received a sum equal to 600,000 pesetas, about $120,000. Dubois received $20,000 and the title of baron for attending the wife of Napoleon. The latter declared that he did not believe in physicians, but he averaged over $40,000 a year paid to doctors, dentists, and chiropodists. Sanz describes the public health officials in the towns of the Romans, saying that they were officially organized and passed on the credentials of those wishing to practice medicine. A fine of 2,000 *drachmas* was imposed on those practicing without the official approval of these official *archiaters*. They were exempt from military duty and taxes,and had certain other privileges. The Visigoths continued some of these regulations and added others, one decreeing that if the physician's patient died, the physician could not collect any fee. Coming down to modern times, Sanz remarks that an American trust magnate or a Mexican cotton king now pays for medical attendance twenty times more than the kings and popes of the past, even though the Roman physician Crina left an inheritance of 10 millions *sestertii*.

Present Status of Epidemic Meningitis.—Marañon concludes his study of meningitis by urging isolation and treatment of germ carriers. They must be sought in those surrounding the patient, but it is impossible to isolate them all, which would be the ideal. At least they can be warned to keep away from other persons as much as possible, and especially from children, and be taught to disinfect the throat repeatedly. In schools and barracks, the carriers must be scrupulously isolated. Preventive vaccination is said to have given good results in a few cases, and this is certainly promising for the future. Serotherapy must be with large doses. In one of his cases he injected 120 c.c. of the antiserum in the course of five days. In very severe cases he has good results from rinsing out the spinal cavity. At first 50 or 60 c.c. of spinal fluid is withdrawn and then the same amount of saline is injected through the same needle. The foot of the bed is then raised for two or three minutes, and again 50 or 60 c.c. of fluid is withdrawn, reinjecting an equal amount of saline. After thus rinsing out the spinal cavity, the antimeningococcus serum is injected and left. Rosenthal recently advised using two needles, a large and a small, for continuous lavage. In most cases marked improvement followed. When the ventricle has to be punctured, the meningitis having become walled off, this will be found easier in children. The mortality was 78 per cent. in the thirty-three cases he has found on record in recent literature. He reviews the entire field of treatment, and warns to be on the alert to ward off bed sores. After the first two or three days the patient can begin to eat milk, eggs, purées and so forth, even although the temperature may still be high.

Treatment of Felon.—Sicilia emphasizes that a felon is by no means a harmless thing, and urges extremely vigorous measures. He has attained the best results with tincture of iodin, cauterizing occasionally with zinc chlorid or copper sulphate, removing the dead bone if necessary. In one case a cure was realized only after the entire arsenal of measures had been applied, including staphylococcus vaccine.

Constitutional Predisposition to Disease.—Calleja uses the term crasiology to denote the congenital predisposition to disease. The organic constitution, the true crasis, is always morbid, and is different in each individual. No one has an absolutely perfect constitution. He thinks there is a vast field here for research on ways and means to improve the constitution of individuals. Physicians should be trained as "crasiologists," as he thinks that in the near future this will be a principal part of medicine instead of the subordinate place it occupies at present.

Occult Blood in the Spectroscope.—The first issue of this exchange for 1918 and the number for July 6 were received Feb. 13, 1919. Snapper expatiates on the importance of spectroscopy for determining the presence of occult blood in the stools. He declares that this is so important that no one should hesitate to acquire a spectroscope and perfect himself in its use. The color reactions are not dependable, peroxidases in the absence of blood being liable to give positive reactions, while the blood may be absorbed in the intestinal canal and none reach the anus or be eliminated in a porphyrin combination. With the spectroscope we have two means of determining the presence of blood, the spectrum for hemochromogen and the spectrum for porphyrin. When the blood is eliminated in the form of a combination of porphyrin, it does not respond to any of the color tests for occult blood. All the hemoglobin may be transformed into this hematoporphyrin combination, even when there may be considerable blood in the digestive tract.

Psychopathology and Crime.—Swaep's article was the presidential address opening the sixty-ninth annual meeting of the Netherlands Medical Association. He expatiated on the importance of the connection between psychopathology and crime and its relation to the future of the race, saying that progress in hygiene and in medicine has led to survival of many mentally and physically substandard individuals, and their offspring present many problems, financial and others. "But no backward step in this line is even thinkable. The love for our neighbor is the physicians' best possession, recognizing no frontiers or nationalities.. But although we hold this love for our neighbor sacred, yet we are also justified in listening to the dictates of common sense, if only this voice of our reason rings out true and clear, if only our ideas are pondered well and a hundred times tested. Nowadays the problem of hereditary transmission is at the zenith of interest. Everywhere we meet it, in the study of character, of mental and organic disease, in degeneracy, etc. We know more now than ever before of hybridization, of correlations, of dominant and recessive characteristics. Love is no longer a matter that concerns two persons alone; instead of a *Sache von Zweien* it has become a *Sache von Dreien*. To a certain extent we are bound to what we brought into the world with us. All this knowledge has brought the idea of purifying the race. But it is still too early to think of actively interfering. We have no right, either, to apply here the laws discovered elsewhere. Many persons living honest lives may have a latent tendency to criminality as a recessive characteristic. In order to stamp out criminality completely, these persons would have to be included in the repressive measures. In seeking to prevent hereditary transmission of insanity, the only effectual means would be to prevent reproduction of the family strain not only by the inmates of the asylums but by the relatives that come to visit them. Our duty now is to study these questions. How these strains rise and decline, how the lives of the genius, the average man, the martyr and the criminal differ, and how these are linked together by the bonds of heredity—all this should be recorded over long genealogic periods, in biographies and statistics, before the human hand should interfere. To a large extent this task rests on the medical profession. What finer prospect can be imagined than from the partial records of the many to build up on broad, scientifically accurate foundations a grand work which will point the way to improve the welfare and the character of the race." He added that a society for such research was founded a few years ago in Holland, the Nederlandsch Volk, and Heijmans and Wiersma, among others, have made valuable contributions in this line.

Typhoid Bacilli Carriers.—Aldershoff is public health inspector at Utrecht, and he concludes his dissertation on the subject of healthy typhoid bacilli carriers by emphasizing that the problem is merely one of cleanliness. It is impossible to isolate them all, and a scrupulously careful and cleanly carrier is no danger to his or her ordinary environment. The essential point in prophylaxis is detection of all cases of typhoid in the earliest possible phase and removal to a hospital. Notification of even the suspicious cases should be compulsory, without waiting for certainty. All the vast literature on typhoid carriers and the conclusions, when it has been sought to apply them in practice, have resolved themselves into merely the old laws of hygiene.

*Types of Tubercle Bacilli found in Tuberculous Skin Lesions, especially in Lupus. C. W. Anderson.—p. 1689. Commenced No. 44, p. 1521.
Present Status of Deep Roentgen Treatment. H. J. Panner.—p. 1699.

Types of Tubercle Bacilli Found in Lupus and Other Tuberculous Skin Lesions.—Andersen's experimental research demonstrated in 3 of 30 cases of lupus that the bovine tubercle bacillus seemed to be responsible for the lesions. In 9 the bacilli were of the typical human type; in the others they seemed more or less atypical human tubercle bacilli, except in 4 cases in which he was unable to cultivate tubercle bacilli from the lesions. His research was done on 72 guinea-pigs, 141 rabbits, 7 calves and 4 fowls. Inoculation of the guinea-pigs elicited a positive response in all but 3. These 3 responded to the lupus bacilli as to the bacilli of fowl tuberculosis, but fowls inoculated with the same bacilli did not sicken.

*Habitual Constipation, VIII. T. E. H. Thaysen.—p. 4.

The Ovaries with Hydatidiform Mole.—In Nordentoft's case the woman of 35 had borne three children. There was an interval of three years since the last pregnancy, but recently there had been no menstruation and a tendency to nausea and vomiting had convinced the woman that she was three months' pregnant. Then came severe hemorrhage by the vagina and the uterus seemed to be of a size corresponding to a six months' pregnancy. A large mole was found and the uterus curetted. A tumor rapidly developed thereafter on each ovary. On the left ovary the cystic tumor was 15 cm. long, with a base 8 cm. broad; on the right ovary the tumor was smaller, but both were of cystic structure, filled with a fluid, gelatinous mass similar to the contents of the mole. The uterus itself also showed suspicious patches so that supravaginal amputation seemed advisable. The patient has been in good health during the months since to date. The ovarian tumors had probably existed at the time of the operation on the mole, but their rapid growth, that could be followed with the eye and palpation; within less than a week, was most striking. In six other cases of mole given operative treatment at the same hospital, the women were from 20 to 46 years old; four of the women had borne several children, one only one child, and one was pregnant for the first time. Four have borne healthy children since; one woman died several months later of a pulmonary lesion which may have been metastasis from the mole, and one succumbed to sepsis consecutive to the operation.

Habitual Constipation.—Thaysen discusses the diagnosis, etiology and treatment of chronic habitual constipation, this being his eighth communication on the clinical and roentgenologic aspects of constipation. He defines it as primary, habitual; secondary, symptomatic; and the constipation which is a complication of other lesions. He affirms that the large majority of cases of chronic constipation developing between the ages of 26 (women) or 31 (men) and the age of 50 are of the symptomatic type. This symptomatic form differs materially from the type of habitual constipation, both in the stools and in its clinical course. Habitual—primary—constipation is due to abnormal weakness or abnormal activity of the nervous motor apparatus of the lower bowel; it usually begins before the age of 26 in women and 31 in men. It runs a chronic course with occasional remissions and marked tendency to recurrence, and a hereditary tendency is often manifest. This latter tendency may be indirect, from congenital abnormal conditions in the ductless glands or a congenital overcomplete digestion. Cooperating elements may be lack of hygiene or nervous, medicinal or mechanical factors. He analyzes each of these possible factors in turn and the means to combat them. Ptosis is extremely rarely to be incriminated for constipation in men, but habitual constipation developing between 15 and 20 is as common in males as in females, namely, in 29 and 31 per cent. This, he thinks, disproves the importance of ptosis as a factor. Fully 38 per cent. of all cases of habitual constipation in women begin within the fifteenth year. Excluding from the remaining 62 per cent. the 37 per cent. which are traceable to what he calls rectum constipation, only 25 per cent. are left for which ptosis can possibly be incriminated. These percentages are from his own clinical experience. Of the twenty-three women who formed the 25 per cent. thus left over, only four presented gastroptosis, that is, less than 5 per cent. of the total material. Hence the assumption of kinking of the bowel from gastroptosis as the cause of chronic constipation can apply only to less than 5 per cent. All his experience seems to discredit kinking at the flexure as much of a factor in the genesis of chronic constipation. When there is actual stenosis from a kink or other cause, ileus results in time, while with habitual constipation this occurs extremely seldom, only when there is obstruction from a fecal stone or spasmodic contraction. It is impossible to explain with a mechanical cause for the constipation the frequent remissions which occur in the course of habitual constipation, even of many years' standing. It is a well known fact that the latter may disappear for a time during a trip to the country, or other traveling or under emotional stress. In concluding this instalment of his work, Thaysen remarks that in examining twenty healthy women and twenty healthy men, he found the transverse colon 10 cm. or more below the umbilicus in 20 per cent. of the men and in 50 per cent. of the women, although the position of the stomach was normal in all. He also found that the position of the colon may vary by 8 cm. from day to day.

THORACIC INJURIES

REPORT OF CASES TREATED BY SURGICAL TEAM 39 AT EVACUATION HOSPITAL NO. 8 FROM SEPT. 6 TO OCT. 25, 1918

HOWARD LILIENTHAL, M.D. (New York)
Lieutenant-Colonel, M. C., U. S. Army; Chief, Surgical Team No. 39

WALTER M. BRICKNER, M.D. (New York)
Major, M. C., U. S. Army

AND

W. A. KELLOGG, M.D. (New York)
Captain, M. C., U. S. Army

FRANCE

During the forty-nine days of our stay at Evacuation Hospital No. 8, the team treated 250 patients and performed a total of 340 operations, as contained in report dated Nov. 5, 1918.

There were sixty-seven cases of thoracic injuries, or about 27 per cent. of the whole number of wounded. This high percentage is explained by the fact that Team 39 was assigned the greater number of this class of cases. A number of others not in our list were sent to one of us (H. L.) in consultation, and in most of these, for example, cases of severe fracture of the skull complicated by thoracic wounds, operations on the chest were not performed.

CONDITIONS

The hospital operating room and its accessory departments, preparation, shock, roentgen-ray, etc., were well equipped and excellently managed by Major Arthur Shipley under Colonel Hall, commanding officer. Asepsis was as perfect as could be expected under the circumstances.

Under the plan of the institution there could be no segregation of the different classes of patients at operation; accordingly operation in the malignant gas gangrene cases was necessarily performed in the same room with others that might be clean or at most only under suspicion. Since there were so many of the latter class, however, the actual infection of wounds by the discharges from other patients could not be traced. Also, the proportion of those known to be aseptic at the time of operation which became infected afterward must have been almost negligible. It is believed, however, that the important class of abdominal and thoracic injuries might have been treated to better advantage had there been a special operating room equipped for the purpose.

CONDITION OF PATIENTS ON ADMISSION

Most of the patients arrived within twenty-four hours after being wounded. The shortest period was about four hours, and the longest six days, the latter interval occurring in the case of a German prisoner with two sucking wounds. He stated that he had not eaten during this entire time. He died a few hours after an operation under local anesthesia to close the thorax. About one third of the patients (twenty of the sixty-seven) were in shock on admission, and either had to be treated in the shock ward for from several hours to two days before operation, or the operative treatment, when urgent, had to be modified to suit the case.

A certain degree of vital depression, not perhaps amounting to actual shock, was present in nearly all of our patients, and it is believed that this element of depression caused by fatigue, both mental and physical, by hemorrhage, by hunger and thirst and by exposure, was responsible for that general state which surgeons mean to designate when they use the expression "poor risk."

It was this matter of "poor risk" that caused us to abandon early the idea of attempting to extract every foreign body merely because the immediate operation would probably be easier than it would be later when deforming adhesions and embarrassing exudates would add to the technical difficulties. We therefore reserved the free exploration of the thoracic cavity (described under "Operative Procedures") for those cases in which the foreign body had done such severe damage that repair was urgent, or when it was so large or so dangerously placed that its removal appeared imperative. Thus, a large, rough piece of shell, say 2 by 2 cm. in size, which might reasonably be supposed to have carried bits of clothing into the thorax, would be removed; while a machine gun bullet or a small piece of high explosive shell, which for the present at least was apparently quiescent, might, from the evacuation hospital point of view, be better left than removed by a large operation.

FRACTURED RIBS

The complication of fractured ribs may be considered one of the most dangerous of war wounds of the thorax. It almost invariably leads to infection, especially when numerous spicules have penetrated the lung.

The larger bronchi have been found by many investigators to be the habitat of anaerobic and other microorganisms, while the smaller air passages have been considered sterile. But when these smaller bronchioles have been wounded from without so that a free passage exists from the larynx to the wound, the first cough or other expulsive effort of the patient must drive infection from these larger bronchi directly into the visceral wound. This is a simple mechanical explanation of the almost universal infection of these rib punctures and lacerations in compound costal fractures, and it also explains pretty well the absence of infection in "closed thorax" fractures of the ribs; for here the intrathoracic pneumatic pressure prevents the secretions of the bronchi from being carried to the wound of the peripheral part of the lung. The same danger of infection is present in open (sucking) wounds inflicted by lung-piercing projectiles, while it is often absent when the projectile is small and its track of entrance is closed spontaneously by overlapping tissue planes. Whenever, therefore, there was an open sucking wound of the thorax, great care was taken to "clean up" splinteered ribs and to extract loose fragments from the wounded lung.

There were eighteen of these cases in which ribs had been fractured through large wounds, and of these patients, eight died, a mortality of 44 per cent., a larger death rate than in any other class of thoracic wounds.

"SUCKING WOUNDS"

Sucking wounds are those in which there is a free access of air to and from the interior of the chest. These wounds, when small, are not necessarily dangerous. Traumatic openings, however, when large enough to admit air by suction in quantities as great as or greater than that which enters the lungs through the larynx, give rise to the well known flapping of the soft tissues of the mediastinum with each respiration. This condition is extremely dangerous, not only because it diminishes the amount of intrapulmonary respiratory air in the uninjured as well as in the injured side, but also because the motion to and fro of the heart itself forms the basis of a particularly fatal form of cardiac shock.

Probably the simplest method to overcome this condition for the time being is to close the chest in the quickest possible way, even though it be done by simple skin suture, or, failing this, by firmly covering the wound with soaking wet gauze. If the wound is a very large one, the patient's distress due to the mediastinal motion can be instantly relieved by traction on the presenting lung. This steadies the mediastinum, and a few sutures or even a sterile safety pin holding the lung to the chest wall will for the time being relieve the condition. No great traction force is necessary. The pleura covering the mediastinum is in from twenty-four to forty-eight hours stiffened by exudate, and the peril of the flapping ceases. It is the presence of this stiffening exudate that makes opening the infected chest less dangerous than wounding the normal thorax. Thoracotomy for empyema will illustrate this immunity.

Large sucking wounds also presuppose gross injury to lung and other structures, besides the probable implantation of infected material, such as clothing, etc.

Fifteen of these open sucking cases were treated by us, and there were six deaths—a mortality of 40 per cent.

PENETRATING WOUNDS

In the class of penetrating wounds we include cases in which the missile is within the chest or in the thoracic wall, having passed completely through one wall of the cavity, but with no wound of exit. There were thirty of these, with nine deaths—a mortality of 30 per cent.

COMPLETELY PERFORATING WOUNDS

Completely perforating wounds, with entrance and exit and no foreign body remaining, form a list of twenty-one, with only two deaths, or a mortality of 10 per cent. No large operations had to be performed in these cases. In fact, often the simplest débridement sufficed, especially in the probably aseptic through and through punctures by hot machine gun bullets striking the chest squarely and not tangentially. These patients usually suffer comparatively little. There may have been a little hemoptysis, often a hemothorax relieved by simple emptying by cannula, described farther on, and in a few days there is apparent recovery. But it is well known that these hemothorax cases are sometimes the site of very mild infection with late empyema formation, and some of these simple cases, with no operation or with simple local anesthesia débridement have developed an opposite lung pneumonia from five to seven days after the injury. Also, from observations at Base Hospitals No. 3 and No. 101, it has been learned that patients of this class sent to the base will sometimes develop the most serious infection. The estimation of mortality rate from work solely at the front cannot fail to be misleading.

MISSILES

Bullet and shell fragments injuring the thorax were rather surprisingly similar in percentages of mortality, the difference in those cases in which the character of projectile had been demonstrated being but 2 per cent. There were twenty-two bullet wounds with 27 per cent. of deaths, and sixteen shell fragment injuries with 25 per cent. mortality. This may be accounted for by two factors: Bullets striking the ribs at a slant or tangentially make ugly and destructive wounds, while it is only the smaller shell fragments that give rise to injuries not immediately fatal. So by the time the patients had reached the evacuation hospital, the conditions had been equalized, small, completely perforating éclats often doing little or no more damage than merely perforating machine gun bullets, while the large pieces of high explosive shells killed the men outright.

Illustrating the fact that rifle bullets striking at an unfortunate angle were capable of inflicting injuries of great magnitude, we briefly cite the case of a soldier who was struck by a machine gun bullet near the angle of the eleventh rib. The missile, ranging upward, fractured the next upper five ribs in the same location, and then passed through the external soft parts and out through the axilla. There was an enormous wound on exposing the injured region, the abdomen, diaphragm and thorax being widely torn so that portions of the stomach, spleen, omentum and colon prolapsed into the wound. The abdominal wall and wounded diaphragm were repaired and the lungs insufflated by the intrapharyngeal method so that the left lower lobe presented at the wound. The defect in the parietal pleura, fully 5 cm. in diameter, was closed by suturing the lung to the circumference of the pleural wound. This patient did well, though he developed an opposite lung pneumonia, and when the team left the hospital the prognosis was excellent. There had been no leakage around the suture line of pleura and lung.

Another patient had been struck in a similar manner, the greater part of the left chest collapsing. His condition was not suitable for operation, and he soon died.

One man was struck in the right arm, the missile cutting the musculospiral nerve and not injuring the humerus; then it entered the right side in the axillary line, fifth interspace, traversing the chest and presenting beneath the skin in the fifth interspace, left axillary line. It was removed under local anesthesia. The éclat was 2.5 cm. long (1 inch) and 0.63 cm. in section (1-4 inch square) and weighed 24.5 gm. It had entered "head on" and had apparently maintained its trajectory without "up ending." Yet, excepting a right hemothorax which was emptied by trocar and cannula, no ill effects appeared to follow this and the man was evacuated practically well, within ten days. Theorizing on this strange accident, one is forced to the conclusion arrived at by one of us (W. A. K.) that the projectile struck the posterior wall of the sternum and thence was deflected endothoracically but outside the lung, still traveling in the direction of its long axis until it reached the costal interspace, where it lodged beneath the skin, not having caused enough damage in the left chest to produce a left hemothorax.

HEMOTHORAX

The diagnosis of hemothorax is easy, especially in the recent cases. Flatness on percussion with strong voice conduction are characteristic. The fluoroscopic examination is confirmatory.

The blood may so obscure the screen or plate that foreign bodies even of large size may be missed. A recent hemothorax in a patient whose condition does not seem to warrant a cutting operation should be treated by emptying it with the trocar and cannula of the army general operating set and without forcible suction. The procedure will be described later. An infected hemothorax should be treated as an empyema.

PNEUMONIA OF THE UNINJURED SIDE

Pneumonia of the uninjured side was the commonest and probably the most serious complication that we encountered. Nor did it seem to make any particular difference whether the patient had been operated on or not. It was of the bronchopneumonic type, but the patches as discovered by physical signs and checked up by roentgenoscopy were extensive. The middle and upper parts of the lung were most often affected, the bases rarely. The disease usually appeared from five to seven days after the injury, and in at least three cases it defervesced by crisis and then recurred. We have no theory to explain the incidence of this complication. It reminds one of the so-called "sympathetic" or "reflex" anuria of unilateral acute kidney lesions.

INFECTION BEFORE OPERATION

Four of our patients had advanced infection of wounds before operation, though it is probable that few or none of the wounds were bacteria free. Of these four patients, three died. In one of these Welch's bacillus was present, in one, Welch's bacillus and streptococci, and in the third and fourth the bacteriology was not noted.

ROENTGENOGRAPHY

The roentgenographic department, an indispensable adjunct to modern war surgery, was most efficiently directed by Captain Alleman and his staff. The speed and accuracy with which foreign bodies were localized during a rush of wounded is worthy of high commendation.

In the intelligent after-treatment of chest injuries, fluoroscopy in the vertical posture is a necessity. The apparatus was secured a few days after the arrival of Team 39, and it proved of enormous value, both in determining the presence of exudate, usually blood, and also in confirming the diagnosis of consolidation (pneumonia) of the "other" lung. Frequently the changes in a case had to be observed from day to day, to decide on repeated aspiration or other secondary procedures that might be of vital importance. Fluoroscopy of this kind occupies only a few minutes; it saves plates and films, and gives one a better idea of lung expansion than could possibly be obtained in any other way. The difference in this respect is similar to the comparison of observations made during a surgical operation and those at a necropsy.

We believe that the vertical fluoroscope should be part of the equipment of every evacuation hospital. The amount of current and the size of the tube are much less than are required for making plates.

IMPROVEMENT IN INTRATHORACIC LOCALIZATION

Bodies appearing within the heart shadow and moving with the cardiac impulse are not necessarily within the heart or pericardium. They may be in the lung lying next to the pericardium, and at operation when the lung collapses they may be found far from the heart. Also, bodies within the chest and localized by the roentgen ray may at operation be found at some distance from the point of localization, especially if they are within the lung substance. A better idea of where they will lie when the chest is open may be obtained if after the first roentgenographic examination a cannula is inserted through the thoracic wall and left there long enough for the air to enter and the lung to collapse. A second roentgenographic examination will then often reveal the shadow of the foreign body at some distance from where it was first localized and nearer the point where it will be when the chest is open. We tried it in two cases, and the shadow had moved more than 3 inches. Naturally, this method is unnecessary in sucking wounds.

ANESTHESIA

Unfortunately most of the time ether or local anesthesia had to be employed, because it was not possible to secure the nitrous oxid apparatus until about ten days before the departure of the team.

OPERATIVE PROCEDURES

Major Intercostal Thoracotomy.—A long intercostal incision is made, usually in the seventh interspace, the ribs being separated from 3 to 5 inches or more by means of a powerful retractor. Lilienthal's instrument was used. Exposure and ease of manipulation are better than by any other known method, and resection of a rib is very rarely necessary in these recent cases. All parts of the chest can be easily reached by eye and hand—even by both hands—and the work done is correspondingly safe. The lung may be collapsed or distended by the anesthetist, who forces the ether, gas or air by means of a foot bellows through a tube in one nostril, closing the patient's mouth and other nostril. The demonstrations were said to be most convincing.[1]

These wide explorations were reserved for the serious class of cases referred to earlier in the article. They were sixteen in number, and seven of the patients died—a mortality of 43.7 per cent. Among these was one case in which a foreign body in the pericardium was mistaken for one in the lung.

---

[1] The method of anesthesia has been fully described on page 8 of a paper forwarded, Aug. 19, 1918, from Base Hospital No. 101, Base Section No. 1, to the chief surgeon, American Expeditionary Forces, at his suggestion in the third indorsement of a communication by Lieutenant-Colonel (then Major) Lilienthal to the chief surgeon, A. E. F., dated Base Hospital No. 3, June 15, 1918.

Six of the sixteen patients were in shock, and of these four died, three of gas gangrene.

In three of these large chest operations other major operations had to be performed at the same sitting. None of the patients in this group died.

Several times the original wound was enlarged, with or without resection, and rib-spreader exploration performed.

In three cases the missile had penetrated the chest wall and had lodged in or just below the diaphragm. In two of these, wide exploration made it a simple matter to extract the foreign body and suture the diaphragmatic wound. One foreign body had passed almost through the diaphragm and was dislodged, dropping into the abdomen at the first touch. The patient, however, made an excellent recovery.

In one case there was a wound of the pericardium through the right chest. It was easily sutured through the wide intercostal thoracotomy.

Pneumopexy.—Suture of the lung to the chest wall was done in our cases only to close large defects of the pleura and ribs. The lung is distended by the anesthetist until it lies flush with the thoracic wall, plugging the defect. It is then neatly sutured to the edges of the pleural opening. This was done four times, and in one case the lung suture loosened. This patient had anaerobic gangrene of the chest wall. He was finally evacuated to Base Hospital No. 3 and is now doing well.

Method of Emptying Hemothorax.—With the patient sitting, under local anesthesia, including the pleura, an incision one-half inch long is made through the skin. A medium-sized or large cannula of the army general operating set is introduced. A rubber tube not less than 8 inches in length is attached to the cannula after it is in place and the fluid is running. It may now be siphoned off, and as the chest empties, air takes the place of the bloody liquid. If this air is to be left in, to be later absorbed, the cannula may now be removed. If the air is to be expelled and the lung expanded to the chest wall, the patient is ordered to strain with the glottis closed, and the instant no more air escapes from the cannula the instrument is withdrawn. From 1,000 to 2,200 c.c. of fluid may be quickly, safely and painlessly removed. Also, wounding the expanding lung by a needle point is obviated. If the hemothorax fluid is to be used in transfusing the same patient, it may be collected directly from the tube into a sterile bottle, examined by culture, filtered and citrated. This form of transfusion was practiced by us but once, and the already moribund patient finally succumbed. A hemothorax emptied and shown by culture to be mildly infected (by the staphylococcus) may nevertheless go on to recovery without operation. We encountered one such case, the patient being evacuated, apparently well, in two weeks. We regret, however, that we were not successful in following up this patient after he left us.

Postmortem Examinations.—There were but few postmortem examinations, because no pathologist was connected with the institution and Lieutenant Pettit, an excellent bacteriologist, was too much occupied during the rush period with his laboratory work to perform necropsies. Examinations of this kind were made, however, in all cases in which the cause of death did not appear obvious.

Mortality.—It is believed that all deaths from whatever cause should be reported. Notes of thirteen of our fatal cases appear here from histories. The facts in the three others are given from our tabular notes, but unfortunately the histories are missing. Copies of these are in the books of Evacuation Hospital No. 8.

REPORT OF CASES

Case 1.—G., who was in shock, had been wounded by two foreign bodies; the fifth and sixth ribs were splintered on their convexities. A major intercostal thoracotomy was performed, and both foreign bodies, which were loose in the chest cavity, having traversed the lung, were removed. The wound was clased without drainage. There was gas gangrene of the wound. It was at once opened widely and even debrided. The process appeared under control, but the sloughing entered an intercostal vessel and there was great hemorrhage. Transfusion was performed. This was followed by improvement, then gradual deterioration, and death four weeks after operation. Postmortem examination disclosed general gas infection.

Case 2.—F. had a nonsucking penetrating shell wound with two fractured ribs in the left chest. He was in shock, but a major thoracotomy was performed to find the foreign body and to remove rib splinters which had wounded the lung. The foreign body was removed. The patient died four days later of gas gangrene.

Case 3.—T., who was in shock, had fractured ribs and an open sucking wound. He died following simple closure of the wound.

Case 4.—P. was in shock. A machine gun bullet had wounded the inside of the mouth, fracturing the lower jaw near the median line. Another bullet had entered the left chest, fracturing the sixth and seventh ribs and coming to rest apparently in the pericardium, moving freely with each heart beat, as determined by fluoroscopy. Major thoracotomy was begun under local and continued under general anesthesia. The pericardium was explored after a searching of the entire right chest had disclosed wounds of the lung apparently of entrance and exit. No bullet was found in the pericardium, which was then sutured. There was no blood in the pericardium. Death occurred in a few hours, and postmortem examination disclosed the bullet in the right lower lobe of the lung. It had evidently lain against the heart and within its fluoroscopic shadow, and had not moved outside the shadow, though kicked by the heart at every beat. This case and Case 13 stimulated one of us (H. L.) to invent a method that might prevent such errors in diagnosis; it has been described under "Roentgenography."

Case 5.—T. had received a large sucking wound of the right scapular region. It was closed by muscle flaps. The patient died in three days.

Case 6.—G. had a sucking chest wound, which was repaired. There was complete paraplegia below the nipple line. The cord had been injured.

Case 7.—J.[2] had a foul wound. The chest was drained of 200 c.c. of decomposed blood. There were sepsis and pneumonia.

Case 8.—H. had received an abdominothoracic wound by a bullet entering the left back at the tenth rib. The bullet was seen in the right iliac region by roentgen ray. It was easily found wrapped in omentum and removed. There was hemoperitoneum from a large wound of the spleen, which was removed through a second (left) incision. The chest was not operated on. The patient died in three days of extensive gas infection of the left abdominal wound.

Case 9.—P. had a large foreign body in the upper lobe of the left lung—a piece of shell that had passed through the lower lobe. The patient had been in the shock ward for twenty-four hours and was not in good condition at operation, which was an easy major intercostal thoracotomy. The foreign body was removed and there was primary union of the wound, but on the fourth day, opposite lung pneumonia appeared, and the patient died three days later.

---

[2] Tabular notes only. History not found.

CASE 10.—C. was operated on twenty-four hours after having received a gunshot wound just below the point of the left shoulder, in back. There was no wound of exit. The patient was in shock. He had been observed over night because he was too poor a risk for operation. Roentgenoscopy revealed a foreign body in the ninth space, near the spine. Intercostal thoracotomy and rib-spreading were performed for tension pneumothorax. The bullet was loose and easily removed. The upper lobe was atelectatic. The fourth rib was fractured. There was hemothorax. The patient died in three days of gas bacillus and streptococcus infection.

CASE 11.—S. had received multiple injuries of the left forearm, elbow and humerus. The missile entered the chest in the region of the left scapula; there was no wound of exit. The patient was too weak for an operation on the thorax. He died some days later from pneumonia of the opposite lung. There was no thoracic operation, except for a slight débridement.

CASE 12.—C. had had the seventh, eighth, ninth and tenth ribs fractured near the angles by a machine gun bullet. He had a "stove-in" chest and a sucking wound. The wound was sutured and the chest strapped. No radical operation was possible. The patient died in thirty-six hours.

CASE 13.—R. had received wounds in both sides of the chest, but a *large* foreign body, measuring 5 by 1 cm., was reported in the left chest. Large exploration, by intercostal thoracotomy, detected no foreign body, and the patient died on the table. Immediate examination revealed hematopericardium and a *small* foreign body within.

CASE 14.—D. had an infected bullet wound with fractured ribs. Thoracotomy was performed. The Welch bacillus was present. The patient died from pneumonia of the opposite lung. The wound had nearly healed eight days after operation.

CASE 15.—T.[2] had an open sucking wound of the back with rib fractures. After closure, he died in forty-eight hours.

CASE 16.—W.[2] had an open sucking wound with fractured ribs. Death occurred soon after closure.

SUMMARY

Of the total of sixty-seven thoracic cases that passed through our hands, sixteen, or 23.8 per cent., were fatal. Fifty-one of these patients were operated on, and fourteen, or 27.4 per cent., died. Sixteen patients were not operated on, and of these only one, or 6.2 per cent., died. This does not mean, however, that operation is responsible for the large proportion of deaths. Of the sixteen patients not operated on, four were in severe shock but with small wounds; one of these patients died. The other twelve apparently were cases that demanded no operative therapy. Yet it is recognized that infection and empyema may, in some cases, have developed after evacuation.

These statistics, together with what may be gathered from the preceding report, may be taken for what statistics are worth. They compare most favorably with the general figures in the literature.

CONCLUSIONS

1. The wounds seen in evacuation hospitals may be divided into two classes: (A) Those which demand repair of obvious injuries to the chest wall, such as large open wounds or extensive fractures of ribs with probable injury to lung. (B) Injuries to the lung, or large foreign bodies in the thorax which demand exploration.

Wounds in Class A should be treated on ordinary surgical principles and the wound closed as well as possible. In the presence of large defects in the pleura, stopping the opening by suturing the inflated lung as a plug should be performed when there is not sufficient other tissue for the purpose.

Wounds in Class B should be operated on by what I have denominated major intercostal thoracotomy without resection of ribs. With the aid of a well constructed rib retractor an ample opening can be made through which all parts may be clearly inspected and through which operations on the lungs, diaphragm and most parts of the chest wall can be performed with comfort to the operator. In concluding the operation the ribs may be easily brought together and the pleura fully approximated by three pericostal sutures of absorbable material (kangaroo tendon or chromicized catgut). Whether or not there should be approximation of the skin is a matter to be decided in each case.

2. There may be combinations of Class A and Class B by extending an already large wound in any part of the chest. The principle of visual exploration with the aid of a rib spreader can be here applied.

3. Some kind of forced anesthesia, such as the intrapharyngeal method already referred to, is absolutely necessary in treating recent wounds of the thorax by full exploration.

4. All thoracic wounds should be under observation for not less than ten days at the evacuation hospital, and, even then, we are not sure that complications, mechanical or by infection, may not occur at a later period.

5. Pneumonia of the opposite lung is the greatest immediate danger in these cases. While its cause is unknown, we should guard the patients against cold and exposure, especially during the change of dressings.

ACUTE TRAUMATIC ATELECTASIS

Atelectasis has been frequently noted by operators, and we have never heard a satisfactory explanation. It usually occurs in the neighborhood of a wound and is far more than an ordinary collapse of the lung. It is usually unilobular, the lobe being contracted to its smallest possible size. The tissue feels soft and not infiltrated. I would suggest that animal experiments be undertaken to discover the cause of the atelectasis, and I would also advance the theory that it is a true spastic condition of the lung caused by visceral muscular contraction, often but not always in the effort of nature to draw the lobe away from a point of peripheral irritation.

Mental Diseases in New York During War Period.—H. M. Pollock, statistician of the New York State Hospital Commission, in an article on the subject named in the *State Hospital Quarterly*, February, 1919, published by the hospital commission, offers the following figures and conclusions: Comparing the admissions on account of mental diseases for the period 1911-1914 with the period 1915-1918, there was an increase in senile cases of 5.5 per cent., in general paralysis of 14.2 per cent., a decrease in alcoholic cases of 22.3 per cent., an increase of 17.5 in the manic-depressive and allied groups, an increase of 37.9 in involution melancholia cases, an increase of 42.9 per cent. in dementia praecox and allied forms, and a decrease of 12.5 per cent. in the psychoneuroses. It can reasonably be inferred that the war, like all great emotional disturbances, has been a precipitating factor in the causation of some forms of mental disease among the civilian population. Patients under treatment in the institutions for the insane in the state increased more rapidly during the war. The increase was due in part to the accumulation in the hospitals of deportable aliens. The ratio of first admissions to the general population of the state increased during the war period. The rate of alcoholic insanity decreased during the war, especially in the years 1915 and 1918.

EFFECTIVE MALARIA CONTROL IN A RICEFIELD DISTRICT

WITH OBSERVATIONS ON EXPERIMENTAL MOSQUITO FLIGHTS

J. C. GEIGER, M.D., D.P.H.
W. C. PURDY, M.S.
AND
R. E. TARBETT, S.B.
Epidemiologist, Plankton Expert and Sanitary Engineer, Respectively, United States Public Health Service
LONOKE, ARK.

In a previous publication,[1] there was given in detail the endemicity of malaria in two rice districts, one in Louisiana and one in Arkansas. In the Arkansas district, known as the Extracantonment Zone, Ebert's Field, and including the town of Lonoke, various intensive control methods have been used continuously during the year 1918.

LOCATION

The field is located about one-fourth mile west of the western limits of Lonoke, a town with a population of approximately 1,500. The field was located in an area used during 1917 for the cultivation of rice, and the area to the west and south is now used exclusively for rice cultivation.

TOPOGRAPHY

The entire area is flat with very slight slopes toward the streams and the divides undetermined. The top soil is what is commonly called gumbo, underlaid at a depth of 2 or 3 feet with an impervious clay stratum. Owing to the flat slopes and the impervious character of the soil, natural drainage is poor.

RICE CULTURE

From a topographic and geologic standpoint, the section is particularly well adapted to rice cultivation, and the greater part of the prairie land is under cultivation, as shown in the accompanying chart. With the establishment of the Flying Field, an agreement was made whereby no rice should be cultivated within 1,500 feet of the boundaries of the field, thus bringing the first ricefield to the west 1 mile from the barracks and to the south three-fourths mile from the nearest camp building.

The results that we are recording in this short article are remarkable, for malaria has been entirely eliminated among the civilian population, in spite of the fact that for the previous summer the history incidence index demonstrated the prevalence of chills and fever in twenty-nine out of every 100 inhabitants.

METHODS OF CONTROL

The principal methods adopted to control the disease were: (1) sterilization of carriers to prevent the infection of mosquitoes; (2) screening, to prevent the access of mosquitoes to men, and (3) limitation of the production of mosquitoes, as far as was found practicable.

1. *Human Carriers.*—Two separate blood indexes (thick smears) were made of every resident in the Lonoke district. The taking of these indexes required a large amount of educational work in the community, in order to develop the spirit of cooperation, for we were operating in a community in which malaria control and laboratory diagnostic methods had never been used before, and a natural individual tendency existed against the taking of blood smears. The index results recorded in a previous article were low but interesting, if one compares the gradual seasonal increase and the evident importance of the carrier in the malaria case rate for the coming summer. The taking of blood smears and the checking up of the residents were accomplished by making card indexes of the occupants of each house, store and building. As far as possible, examinations were made of new residents, also.

Quinin Sterilization of Carriers: Of the persons from whom thick blood smears were taken, ninety were found on microscopic examination to be carriers, every one of whom was treated with quinin in capsules by mouth, a dose being 10 grains a day, preferably taken at bedtime. Each carrier treated was followed for thirty days so as to make certain that the treatment was actually carried out. At the end of thirty days, individual patients were given quinin sufficient for a like period of time, with instructions to use as in the first period. Of the entire number, only 10 per cent. followed out in its entirety the treatment of 10 grains a day for the sixty days. We were checking the discovered carriers microscopically each month, so, what with laboratory methods and a careful study of their history, there was no possibility of our missing any relapses in any given patient. The last blood examination was made in September, all carriers proving negative.

Peculiarity of Carriers: Not all of the foregoing carriers were discovered at the initial time of the making of the indexes. In five cases, the second dose of typhoid vaccine precipitated a chill, which prompted us to examine the blood. In all, many plasmodia (signet rings) were found. The blood of these patients had proved negative twice before. The same result was obtained when another carrier had been vaccinated against smallpox, evidence of a positive "take" having just been noticed. Why the second dose of typhoid vaccine and not the first or third precipitated a paroxysm is an interesting problem.

The results on the same people as shown by the indexes point to a seasonal variation, which is important if one should desire information as to the maximum malaria incidence. Many carriers showed parasites curiously resistant to the stain. Active exercise and fatigue evidently played an important rôle in the appearance of parasites in the peripheral blood. In some cases among new residents who had previously given a typical history of chills every other day and whose blood was negative on microscopic examination, the blood became frankly positive under these physical conditions. This may explain why, in the case of two untreated carriers examined every day for a month, in one we were able to obtain only two additional positives and in the other only three. The observed fact, as regards these two carriers, that the positives were obtained near the evening hours, with negative results in the morning, is likewise interesting. Probably the most important peculiarity of the malaria carriers was the fact that in nineteen there was absolutely no history of chills and fever or of any symptoms suggesting malaria, active or latent, in the previous three years.

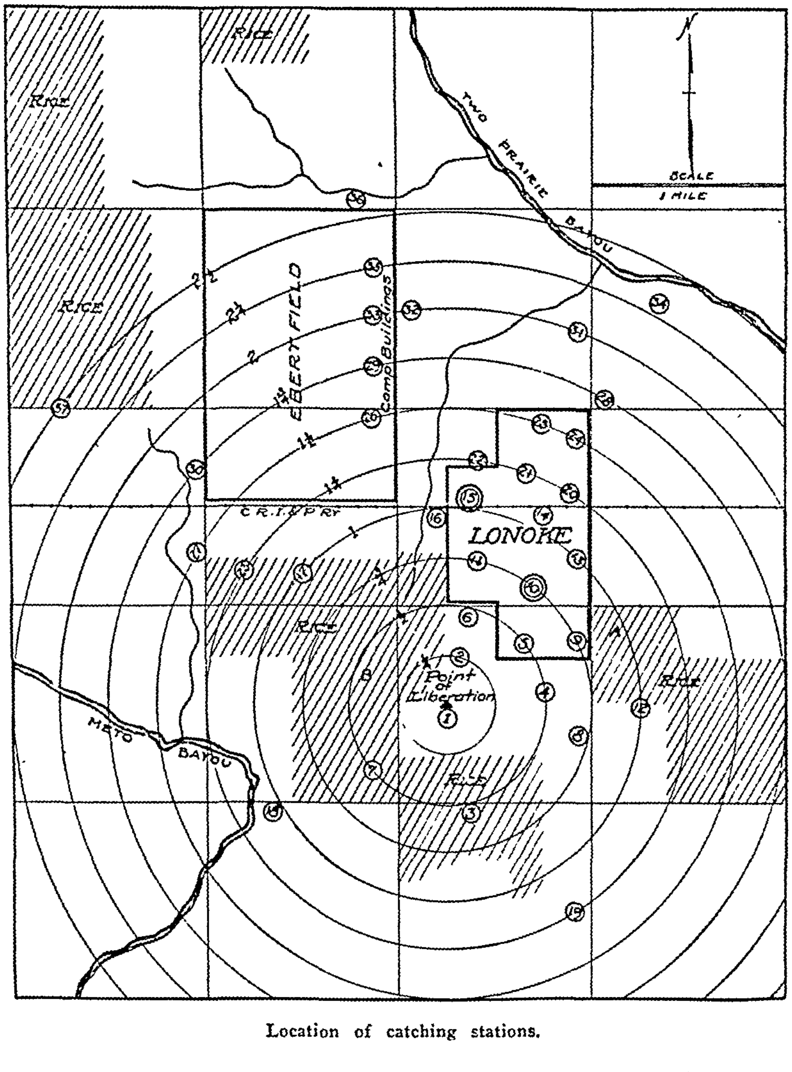
2. *Screening.*—Beginning in January, and following a house to house survey, requirements for screening, including specifications as to the size of mesh, namely, from sixteen to eighteen meshes to the inch, were published and a definite date set for complete fulfilment. All public buildings in which any gatherings at night would occur, such as churches, were required to install vestibuled screened doors in addition. No open-air gatherings were allowed. On the basis of reasonable screening, negro cabins were separated into three possible classes, uninhabitable, repair possible, and good. Monthly inspections of screening were made. The importance of this control measure is obvious when one considers that only 10 per cent. of houses, stores and buildings had met the requirements at the time of the initial inspection.



Location of catching stations.

3. *General Measures.*—For mosquito control operations it has been assumed that the area within which operations must be carried on shall extend at least 1 mile beyond the limits of the area to be protected. On this basis the control area necessary for the protection of both Ebert's Field and the city of Lonoke comprises approximately 13 square miles, which area includes both the field and the city.

Control by Drainage: With the exception of the bayous, the streams in the area had no well defined channel or bed. Surface drainage, in fact, practically all the drainage from the ricefields, was taken care of by road ditches. These ditches were faulty in construction and in many cases were without outlets.

The work necessary, in order that the water surfaces might be reduced to a minimum and the proper conditions maintained for efficient control over mosquito breeding, required the clearing and channeling of the existing waterways, the clearing of old ditches, and the construction of new ditches that were necessary for the draining of swamp areas and for the prompt removal of water from the ricefields. This work required the clearing of 10 miles of stream-bed and the ditching of 60 miles of ditches varying in depth from 8 inches to 3 feet.

Control by Oiling: With the commencement of breeding, during the latter part of April, oil control measures were instituted, and from that date until the close of the breeding season all water surfaces within the area, with the exception of the ricefields proper, were sprayed with oil at intervals not greater than seven days. Owing to frequent breaking of ricefield levees, intentional and unintentional, and the discharge of water containing mosquito larvae and pupae, close inspection and frequent applications of oil were required, in order to prevent production. Constant inspection was made in checking the results of the control work.

While control measures did not affect breeding within the ricefields, they did confine all breeding to these rice areas. With these prolific breeding places present within the district, entire absence of mosquitoes could not be expected; but local information showed a marked decrease in numbers over those of previous years.

Control of mosquito production being humanly impossible so long as the ricefields were within flight distance of any and all parts of the area, it is interesting to compare the mortality and the history incidence of malaria in 1917 with the case reports, mortality and September check index of 1918. In 1917, there occurred four deaths from malaria in the control area against none in 1918. The history incidence index, 29 per cent., or, expressed in the number of cases, 522, the only available record for 1917, when compared with the actual development of only one case in 1918, is conclusive proof of the efficiency of the control.

This is remarkably demonstrated by the September check index (thick smears) taken of every resident in the area, the result giving a percentage of 1. As final evidence there were the continuously negative findings of infection on dissection of *Anopheles quadrimaculatus,* the only *Anopheles* breeding in the area.

In order that a comparison of results obtained in the September check index might be made with the results obtained in communities adjoining but outside the control area, indexes were made on two uncontrolled bayou bottom sections. The results of these indexes, based on a limited number of persons, showed 7 per cent. in one case and 4.5 per cent. in the second.

Since in spite of the attempt to control production, *A. quadrimaculatus,* recognized as an efficient vector of malaria, was present in large numbers about the residences of the community (as may be seen from Table 1 illustrating the flight experiments), this diminution of malaria can be ascribed only to screening and the sterilization of the human carriers—the latter being probably the main factor.

FLIGHT EXPERIMENTS

May 25 ricefields A and B were flooded. After an interval of from fifteen to twenty days, and before any of the other fields in the area were flooded, *A. quadrimaculatus* was observed more or less throughout the city and in the area adjoining and to the east of the aviation field. Since control measures within the zone were at that time excellent, it was most probable that the mosquitoes observed came from the ricefields just mentioned, in which fields production was great. If this was the case, the flight distance was as great as 1$\frac{7}{10}$ miles, a distance considerably greater than that observed by Le Prince and Griffitts[2] in South Carolina, where the greatest distance found was slightly greater than 1 mile.

In order that these observations as to flight might be checked, flight experiments were planned.

Any flight experiment in this section would of necessity be of a somewhat more complicated nature than an experiment conducted in a rural community, since here we have a compact community of 1,500 people within 1 mile of a camp of 1,200 men, affording a maximum of available food material.

The experiment consisted of catching, staining and liberating at a given point *Anopheles quadrimaculatus* mosquitoes, and the recatching for examination at given distances from the point of liberation, these distances being at one-fourth mile intervals. The time interval between liberation and the start of recatching was set at sixty hours.

The experiment was begun, August 27, on which date approximately 5,000 mosquitoes, all of which were *A. quadrimaculatus* and about four fifths of which were females, were caught. Practically four fifths of the mosquitoes were caught in sheds and on screens at Stations 5 and 9, and the balance at Stations 32 and 36, as shown in the chart.

After catching, the mosquitoes were put in containers made from lantern globes, the open ends being covered with bobbinet, and were later transferred to the laboratory for staining.

The mosquitoes within the lantern globe containers were stained by spraying them through the bobbinet mesh with an atomizer.

A 1 per cent. eosin solution was first tried, but it was found that this stain was not readily discernible on examination of the sprayed mosquitoes. A 1 per cent. aqueous solution of methylene blue was found to give more satisfactory results, and this stain was therefore used.

As would be expected, a certain number of mosquitoes were killed, owing to heat, confinement and other causes, but, at the time of liberation (nine hours after catching), approximately 4,000 were alive and active.

The stained mosquitoes were liberated at dusk at a point southwest of the city, near one of the flooded ricefields, this point being shown on the chart. At the time of liberation, the weather was clear and warm, and only light air currents from the southwest were prevalent.

A period of sixty hours elapsed between the time of liberation and the beginning of the recatch, the weather conditions remaining unchanged during this interval.

Recatching was started on August 30, and was continued through the period to September 7. During the period of the recatch, the weather conditions changed to cloudy with some rain, September 2, 3 and 4, remaining cloudy on the 5th and 6th, and clearing on the 7th. During the period of recatch, there was no wind, and such air currents as existed were from the southwest.

Recatches were made at points or stations located at definite distances from the point of liberation, and at distance intervals of one-quarter mile. Each collection station included a group of buildings, and mosquitoes were caught in sheds and stables, under houses and on screens.

Catches were made at thirty-seven different stations located as shown on the chart. As will be noted, the greater number of the stations are located to the north, since here was the greater congestion of possible food material. The stations to the west and south

represent every group of farm buildings within the area. At all stations at least one catch was made, while at several stations two or more catches were made on different dates. Table 1 gives the detailed information as to catches and types of mosquitoes caught. No attempt was made to catch any except *Anopheles*, but, as would be expected, a few *Culex* mosquitoes were included.

The total number of mosquitoes caught, by distance from point of liberation, may be seen in Table 2.

Examination of mosquitoes was made by adding a drop of solvent (alcohol, 3 parts; glycerin, 3 parts; chloroform, 1 part) to each mosquito placed on glass over a white back ground and by then observing evidences of the color by use of a small magnifying glass. At the time of examination for stain, observations as to the type and sex were made.

RESULTS

Of the total number examined, only ten were found showing evidences of stain, these all being caught on August 30, the first day of catching. Nine of these, all female *Anopheles*, were found on the screens of one house at Station 10, three fourths of a mile from the point of liberation, indicated on the chart by a concentric circle. One was found on the screen of a house at Station 15, one mile from the point of liberation.

Of the total of 19,831 mosquitoes, 19,238, or 97 per cent., were *Anopheles quadrimaculatus* and 597, or 3 per cent., *Culex*. But one type of *Anopheles* was caught, *A. quadrimaculatus*, confirming other observations that this is the one type of *Anopheles* found in this section during the summer months. Of the 19,238 *Anopheles*, 15,915, or 82.7 per cent., were female. While this percentage is that of the total, the percentage varied considerably for the various stations, and at one station in particular, Station 13, the reverse condition prevailed, as males predominated on one day.

In catching for staining, approximately four fifths of the mosquitoes were caught at Stations 5 and 9; and of the ten stained mosquitoes found, nine were caught at Station 10 or in the same general neighborhood. This brings up the question of the homing instinct observed by Carter, Le Prince and Griffitts.

At the stations in and near the ricefields, *Anopheles* was present in large numbers, and catching was carried on for not over one-half hour period at each station. As the distance from the ricefields increased, the number found decreased; and the time spent in a district increased, with a relatively lower catch.

From the results obtained it would appear that in this section at least a flight of 1 mile might be expected, but that with a fairly densely populated district there would be a dissemination of mosquitoes throughout the entire district.

CONCLUSIONS

1. Malaria has been eliminated from a typical ricefield district.

2. The question of flight of *Anopheles quadrimaculatus* may of necessity be regarded from two angles, that of experiment and that of observation. In one, the largest experiment of its kind ever undertaken in the United States, we have a record flight of 1 mile. In the other observation, there has been recorded continuously and on different occasions a flight of 1$\frac{7}{10}$ miles.

3. The use of 10 grains of quinin sulphate by mouth for sterilization of the blood of malaria carriers is evidently efficient for one malaria season if used actively over a period of thirty days.

4. The completely negative clinical history of the nineteen malaria carriers discovered on microscopic examination indicates, on the one hand, an immense difficulty in obtaining complete malaria control but emphasizes, on the other hand, the importance of the detection of the human carriers.

PROPHYLACTIC USE OF MIXED VACCINE AGAINST PANDEMIC INFLUENZA AND ITS COMPLICATIONS

AT THE NAVAL TRAINING STATION, SAN FRANCISCO

A. J. MINAKER, PH.G., M.D.
Lieutenant, M. C., U. S. N. R. F.
AND
ROBERT S. IRVINE, A.M., M.D. (SAN DIEGO)
Lieutenant, M. C., U. S. N. (T.)
SAN FRANCISCO

The fact that the recent influenza pandemic did not reach the Pacific Coast until about October 1, or more than a month after its appearance in the East, gave time to attempt a defense against it. The problems presented to Commander P. S. Rossiter, senior medical officer, of that period, were: (1) to prevent the entrance of the disease on the station, and (2) to prevent or lessen its spread and complications, should it appear among the personnel.

The U. S. Naval Training Station, being located on an island in San Francisco Bay, more than a mile from either San Francisco or Oakland, made an absolute isolation possible. This was maintained during the height of the epidemic, except for a very rigidly guarded supply boat making trips to San Francisco. To accomplish the second object, daily throat sprays of argyrol, 10 per cent., were administered to every person, and steps were taken to produce a prophylactic vaccine.

The reports available at the time from stricken camps and districts showed a great diversity of opinion as to the exciting cause, but there was general agreement as to the pneumococcus and hemolytic streptococcus being largely responsible for the fatal complications. The recent work of Cecil and Austin[1] at Camp Upton, confirming the observations of Lister,[2] had shown that a high degree of immunity can be produced against pneumonia by prophylactic vaccination.

Although there was difference of opinion as to the etiologic relationship of the influenza bacillus in this disease, and the possibility of conferring immunity against it,[3] a culture of *B. Influenzae* from a fatal case was obtained from the Rockefeller Institute to incorporate in a mixed vaccine.

After receiving the culture of *B. Influenzae* from the Rockefeller Institute, it was found most difficult to reproduce good growths with our ordinary human blood agar, prepared for meningococcic cultures. Therefore, other mediums were prepared and tested, such as streaked blood agar, laked blood agar (human) and rabbit's blood agar; but since the human blood agar titrated neutral to phenophthalein and gave a growth much inferior to that of the rabbit's blood agar of the same reaction and percentage of blood (10 per cent.), and, furthermore, when it was observed that blood from different human donors gave variable growths, from barely perceptible to rather easily discernible colonies, and that the bacilli varied from the fine, minute, evenly stained rods to most bizarre forms, it was concluded that the human blood contained natural immune bodies in varying amounts.

It was found that with any of the foregoing methods in order to grow a sufficient quantity of bacilli quickly to make up vaccine for our needs (20,000 c.c.), a different medium was required. Following a suggestion of Professor Hall of the University of California, the human blood agar when cooled was cooked in a Freas dry oven at a temperature of from 100 to 115 C. or until it changed to a rich chocolate brown; in fact, it was found that even when this agar was apparently overcooked, luxurious growths were secured. Whether this result was due to the destruction of the natural immune bodies, or to a liberation of the hematin from the blood, or to both, remains to be settled. Suffice it to state that with this medium not only could subcultures be easily grown, but also primary cultures from lungs, sputum and postnares demonstrate the presence of *B. influenzae* in easily recognizable colonies. To obtain pure cultures of the pneumococci, human blood agar gave best results, while for vaccine, 2 per cent. glucose bouillon gave ample growths.

The streptococci were grown and gathered from blood agar, 15 per cent. human blood, centrifuged and washed (both washed and unwashed were tried with very little difference noted) and diluted in a 0.5 per cent. phenolized salt solution.

For the gram-positive bacteria the standardizing was done by using Wright's method and counting chamber; the influenza bacilli were counted by ratio with standardized pneumococci.

To arrive at a safe, though effective, dosage of the foregoing bacteria, it became necessary to ascertain if possible on laboratory animals the toxicity of each individually. For *B. influenzae*, the guinea-pig was used, first with dead, and later with live bacilli, neither producing any apparent serious effect in comparatively large doses (3 billion). This coincided with the results of Delius and Kolle's[4] experiments on laboratory animals.

For *Streptococcus hemolyticus*, volunteers were used, 60 million organisms producing no untoward symptoms. The report of Cecil and Austin covering their studies in connection with pneumococcic vaccination of over 12,000 men demonstrated that no ill effects were encountered, that large doses were necessary to give full protection, and that the degree of immunity depended more on the dosage than the interval.

Based on the foregoing considerations, the final composition of the vaccine for each cubic centimeter was decided on as shown in Table 1.

TABLE 1.—COMPOSITION OF MIXED VACCINE

	No. of Bacteria
B. influenzae, Rockefeller strain	5 billion
Pneumococcus Type I, various strains	3 billion
Pneumococcus Type II, regular and irregular, various strains	3 billion
Pneumococcus Type III, one strain	1 billion
Streptococcus hemolyticus, two strains	100 million

These were sterilized separately for an hour at a temperature of 56 C., and then mixed with 0.5 per cent. phenolized salt solution to make the desired amount.

In addition to the foregoing vaccine as suggested by the experiments of Whitmore, Fennel and Petersen,[5] an attempt was made to prepare a lipovaccine: Definite quantities of each culture in the proportions mentioned were removed from plates, dried at 55 C. for one and one-half hours, and then triturated by hand under sterile conditions for eight hours, being moistened with ether from time to time. When completed, microscopic examination revealed a homogeneous mass with no bacterial forms.

To weighed portions of this powder, a sterile mixture of 10 per cent. lanolin in oil of sweet almonds was added and again triturated for three hours; each cubic centimeter of this mixture contained 2 mg. of the bacterial powder.

The effects of this mixture were first tried on a guinea-pig, 1 c.c. being injected with no serious results. Next, five members of the laboratory force were each inoculated with 1 c.c. Their reactions were slightly more severe than the sixteen referred to later, but none lasted more than seventy-two hours. The number of their leukocytes was increased from 4,000 to 8,000, and their serums agglutinated *B. influenzae* 1:200. The injection caused considerable local induration lasting about ten days, but there was no abscess formation.

OBSERVATIONS ON THE VACCINE

Owing to the fact that there were no reports at that time on the use of a mixed vaccine against pandemic influenza, 100 volunteers were given 0.3 c.c. as an initial dose, followed after three days by 0.6 c.c. and two days later by 0.8 c.c. However, before this was done, the temperature of each man was taken and recorded, the urine examined, and the blood from all was used to make a white and differential count. From sixteen men blood was drawn to make agglutination tests with *B. influenzae*, pneumococcus and streptococcus. Eight hours after the first inoculation the temperatures were again taken, with these results:

Before: 98.6 F., 90 men; 99. F., 8 men.
After: 98.6 F., 70 men; from 99 to 100 F., 18 men; 101 F. and over, 5 men.

The white and differential counts evidenced appreciable increase in the polymorphonuclear leukocytes, as illustrated by Table 2.

---

[3] Scheller: Handbuch der pathogenen Microorganismen 5: 1292, 1913.

[4] Delius and Kolle: Ztschr. f. Hyg. u. Infektionskrankh. 24, 1897.

[5] Whitmore, E. R.; Fennel, E. A., and Petersen, W. F.: An Experimental Investigation of Lipovaccines, J. A. M. A. 70: 427 (Feb. 16) 1918.

The reactions recorded twelve hours after the first injection were: trivial, 40; moderate, 53; severe, 8. Trivial signifies headache, very often combined with giddiness and malaise; moderate, headache, backache, chill and slight rise of temperature; severe, all the foregoing symptoms intensified by higher fever, depression and general asthenia associated with multiple pains, in some cases sufficient to require medical aid.

TABLE 2.—WHITE AND DIFFERENTIAL COUNTS

Before		After	
White Count	No. of Men	White Count	No. of Men
6,000 to 8,000	40	6 000 to 8,000	1
8,000 to 10,000	56	8 000 to 10,000	47
10,000 to 12,000	3	10,000 to 12,000	48
		12 000 to 16,000	3
Differential Count Polymorphonuclear		Differential Count Polymorphonuclear	
60 to 70 per cent.	51	60 to 70 per cent.	43
70 to 80 per cent.	46	70 to 80 per cent.	51

The blood of sixteen of these men was secured for agglutination with *B. influenzae* of the type with which they were inoculated, with the results given in Table 3.

Agglutinations with pneumococci and streptococci were unsatisfactory. There was no change in the urinary findings.

As it was considered that the results of the preliminary experiments were satisfactory, general inoculation began, October 12. The vaccine was administered subcutaneously at about the insertion of the deltoid muscle in doses of 0.5, 0.8 and 1. c.c. at three day intervals. In all, 11,179 persons were inoculated, composed of four distinct groups.

1. There were 4,950 persons in quarantine at the Naval Training Station, 171 being hospital corpsmen, transferred after a few days to duty in military and civilian hospitals for influenza cases.

2. At Mare Island Navy Yard there were 1,950 marines released after inoculation, ninety-nine hospital corpsmen on duty in the hospital, and forty civilian employees with unrestricted liberty in the adjacent cities.

3. At the Naval Training camp, San Pedro, Calif., there were 3,100 officers and men with liberty in Los Angeles and vicinity.

TABLE 4.—STATISTICAL DATA

Uninoculated Persons	Population	Influenza No. of Cases	Influenza Per Cent.	Mortality No.	Mortality Per Cent.	Inoculated Persons	Number	Influenza No. of Cases	Influenza Per Cent.	Mortality No.	Mortality Per Cent.
San Francisco and Oakland	625,000	33,065	5.3	3,035	9.2	San Francisco civilians	1,080	14	1.4	0	0.0
Mare Island Navy Yard	8,232	1,296	15.7	65	5.0	Marines at Mare Island	1,950	35	1.8	1	2.8
Nurses and attendants, San Francisco hospitals	550	186	33.8	4	2.1	Hospital corpsmen on duty in influenza wards	270	9	3.5	1	11.0
Los Angeles	600,000	9,124	1.5	612	6.6	Naval Camp, San Pedro	3,100	53	1.7	0	0.0

4. Finally, 1,040 civilian relatives and friends of the personnel of the Naval Training Station inoculated at our shore dispensary, living in San Francisco and vicinity, constituted the fourth group.

A careful record of all inoculated persons showed in the majority a moderate local induration, with some headache, general pains, and slight rise of temperature beginning about six hours after inoculation and abating within thirty-six hours. These symptoms were most marked following second injection. In no case did the constitutional symptoms persist after forty-eight hours.

RESULTS

By means of circular letters, personal investigations, official reports from localities, and from extended reports of inoculated persons during October and November, Table 4 was compiled. In discussing the results tabulated, we can safely omit from consideration the 4,950 men of the Naval Station because they were in quarantine during the height of the epidemic and therefore not exposed. No cases of pandemic influenza occurred during this period, and twenty-four days after release from quarantine, when there were still from 200 to 300 cases being reported daily in San Francisco, only fifteen cases of influenza developed in a personnel of 3,514. These fifteen cases were mild. There was no pneumonia and no fatality.

The inoculations of the 1,080 of the civilian population were completed October 16, which was twenty-one days after the epidemic began in San Francisco, and the incidence and mortality figures for the city represent the period of time, beginning with the inoculation and running until December 1, when the original epidemic subsided. They circulated freely in San Francisco and Oakland during the epidemic and in fifty-four instances assisted actively in the care of their stricken relatives, and apparently escaped the disease. Furthermore, the small number of this group who developed influenza had very light attacks.

The 1,950 marines were inoculated about October 20, about a week after the epidemic began, and were immediately released in Vallejo and San Francisco where the disease was at its height, and owing to the fact that statistical reports were not submitted to the Public Health Service, the personnel of the Mare Island Navy Yard seemed to furnish a fair comparison. Incidentally all of the severe cases developed within ten days after the last inoculation.

TABLE 3.—AGGLUTINATIONS

Before Inoculation	No.	Five Days Later	No.
No agglutination at any dilution	2	No agglutination at any dilution	2
Agglutination at 1:20	7	Agglutination at 1:200	14
Sug. agglutination at 1:100	2		
Sug. agglutination at higher dilutions	0		

The low incidence of the disease in the inoculated persons can only be appreciated when we compare with it the morbidity and mortality of the large population with whom they associated at the same period. We also ask attention to the low incidence of disease of our inoculated hospital corpsmen detailed in military and civilian hospitals in San Francisco, in comparison with the nonvaccinated civilian nurses exposed to the infection under identical conditions.

The 3,100 men from San Pedro Naval Camp were inoculated about November 15, at which time the epidemic was in its recrudescence in Los Angeles and vicinity, and the figures given represent only the cases reported in Los Angeles during the period of twenty-four days following inoculation of the men.

Additional evidence that the men responded to the inoculation of the vaccine was furnished by serologic tests conducted with the strain of *B. influenzae* that had been used in their vaccine. On account of the men being transferred, it was impossible to follow the same group of men in all tests. Agglutinations were made with serum diluted from 1:50 to 1:400; but basing our opinion on our comparative experience, we felt that an agglutination in a dilution of 1:100 should be considered positive.

In Groups 3, 4 and 5, agglutination was also attempted in similar dilutions with a local strain of *B. influenzae* obtained from routine throat cultures on the station during the quarantine. The results are shown in Table 5.

TABLE 5.—AGGLUTINATION TESTS

	No. of Men	Days after Inoculation	Agglutinations Positive	Agglutinations Negative
Group 1	16	5	14	2
Group 2	39	30	33	6
Group 3	11	40	1	10
Local strain	11	40	0	11
Group 4	10	50	5	5
Local strain	10	50	0	10
Group 5	6	70	2	4
Local strain	6	70	0	6

CONCLUSIONS

The facts presented undoubtedly indicate that a noteworthy degree of protection against influenza and its complications was obtained by means of a mixed vaccine freshly prepared from predominating etiologic bacteria. These observations should also encourage further work along the line of immunity against pneumonia. To this end an attempt is now being made to regroup the Type IV pneumococcus with the object of adding it to a vaccine when needed.

ABDOMINAL COMPLICATIONS OF THE INFLUENZA EPIDEMIC AT CAMP CUSTER, MICH.

Major, M. C., U. S. Army

WYNDHAM B. BLANTON, M.D. (Richmond, Va.)
Captain, M. C., U. S. Army

AND

DANIEL N. EISENDRATH, M.D. (Chicago)
Captain, M. C., U. S. Army

CAMP CUSTER, BATTLE CREEK, MICH.

The abdominal complications of the epidemic of influenza in October, 1918, present problems of interest in diagnosis and treatment. The clinical pictures varied so greatly that a grouping of the cases will be of value.

ABDOMINAL RIGIDITY AND TENDERNESS

The question frequently arose as to whether the boardlike rigidity and tenderness of one or both upper quadrants of the abdomen was due to acute abdominal affection or to muscle spasm from lesions of the chest. Some of these cases were seen in the first twenty-four hours of the disease, before the physical signs of a pneumonia or of a pleurisy were sufficiently evident to make a positive diagnosis, all available methods, including the roentgen ray, being employed. The upper abdominal pain, with or without accompanying rigidity, which is seen in acute thoracic disease, has always been held to be reflex. Two cases of pneumonia following influenza showed at necropsy localized fibrinous subphrenic peritonitis of limited extent early in the disease, and it seems certain that there is an actual pathologic basis for at least some of these cases of upper abdominal rigidity.

PAIN IN THE RIGHT LOWER QUADRANT

A number of patients were either admitted directly to the surgical wards or seen in consultation in the medical wards for pain in the right lower quadrant. Pain of a dull, aching character referred to the right lower quadrant was the most prominent feature. On examination there was only slight rigidity in a small number, and in the majority there was tenderness over the region of the appendix, but no rigidity. These abdominal signs and symptoms might ordinarily be diagnosed as appendicitis. However, it was repeatedly observed that the local abdominal signs disappeared in a short time; more rarely they persisted and increased in severity so that operation was deemed imperative. This group occurred in influenza patients, nearly all of whom later showed demonstrable signs of bronchopneumonia.

Another group, occurring during the epidemic, neither accompanied nor followed by pneumonia, was made up of a small number of fulminant cases of appendicitis. Operation seemed imperative and was performed under local anesthesia with good results.

PERITONITIS

Of 140 cases of bronchopneumonia following influenza coming to necropsy in all stages of the disease, six (4.2 per cent.) have shown acute peritonitis. Of the six cases, two manifested themselves as local inflammations in the upper left quadrant and were characterized by flakes of fresh fibrin adherent to the spleen and the contiguous surface of the diaphragm. The four remaining cases were generalized. One was extensive, 1,000 c.c. of thick greenish yellow pus being present in the abdomen. Another showed only a few cubic centimeters of pus, and, though generalized, the site of the greatest change was on the adjacent surfaces of the liver and diaphragm. In a third case there was no fluid, but a delicate coat of fibrin formed a layer over the surface of the stomach and the intestinal coils. A fourth case of generalized peritonitis will be referred to under subphrenic abscess. The fact that the process was twice localized to the upper quadrant, and once, while occurring generally distributed throughout the peritoneum, appeared most advanced over the hepatic surface, suggests an origin by direct extension through the diaphragm. In three cases there was a concurrent accumulation of pus on the corresponding pleural side of the diaphragm. On the other hand, a bacteremia was demonstrated in two of the cases during life, and in the heart's blood at necropsy of all except one (this patient had previously been embalmed). In every instance a hemolyzing streptococcus was recovered. In two of these cases pericarditis was an accompanying finding, and in one, jaundice was present. In addition to a bronchopneumonia, which was in most cases resolving, pleurisy was present. It seems certain, therefore, that with hemolytic streptococci in the blood stream and the accompanying involvement of other serous membranes, the peritoneal infection was hematogenous in origin and did not in all cases originate by the more difficult transdiaphragmatic route. In none of these cases was the appendix or gallbladder the site of any change except on the serous coat, as an incident to the general infection of the peritoneum.

After the first inflammatory reaction, a streptococcus infection is prone to proceed even to the point of a large amount of purulent exudate with only a few localizing symptoms or signs. Extensive exudate in the chest cavity is at times found only after the most critical routine examination when there are no signs or symptoms referable to the chest. Similarly a diffuse purulent peritonitis may be present as a part of a generalized infection without attracting especial attention to its presence through the symptoms usually associated with this condition.

In five of the six cases of peritonitis that were found at necropsy, a diagnosis of such a complication was not made during life, although these patients were carefully and repeatedly examined with the possibility of abdominal lesions in mind. The peritonitis was not secondary to any demonstrable abdominal focus, but apparently was merely one manifestation of generalized infection, which frequently was also evident in pleura and pericardium. Suppurative peritonitis was not found in necropsies in the early fulminating cases of the epidemic, but appeared as a part of the late postpneumonic complications, five of the six cases being found in the last thirty necropsies. The early occurrence of deaths did not afford time for the development of this condition. A similar group of cases was noted during the severe infections in the early part of 1918.

SUBPHRENIC ABSCESS

Two cases occurred during the latter portion of the present epidemic which show the necessity of thorough routine examinations:

REPORT OF CASES

Case 1.—A soldier, admitted, Oct. 8, 1918, with bronchopneumonia involving the right and left lower lobes, complained, November 25, of severe pain in the left upper quadrant of the abdomen. There was slight distention but no rigidity. November 26, 425 c.c. of amber fluid were aspirated from the left pleural cavity, cultures from which showed no growth. November 29, 75 c.c. of pus were aspirated from the same pleural cavity and showed a pure culture of staphylococci. The following day the left chest was again aspirated and a serohemorrhagic fluid obtained through the ninth intercostal space, between the posterior axillary and scapular lines. On pushing the aspirating needle slightly deeper, a thick yellow pus was obtained. Roentgenoscopy had revealed the presence of fluid in the left pleural cavity; hence the outline of the diaphragm on this side could not be seen. A costectomy was performed over the area from which the pus had been aspirated, and 1,500 c.c. of serohemorrhagic fluid were evacuated. The diaphragm was seen to bulge upward and, for this reason, the presence of a subphrenic abscess on this left side was suspected. December 4, the roentgen ray revealed a dense shadow from the sixth rib downward on the left side, and the domes of the diaphragm on the two sides were at about the same level. The normal clear area below the left dome, due to the gas bubble in the stomach, was absent. The tenth rib was resected in the midaxillary line after exploratory puncture had confirmed the diagnosis of a subphrenic abscess. Following the needle, which had been left in situ as a guide, the pleural reflection was pushed upward, an incision made through the muscles of the diaphragm, and 125 c.c. of a dark pus were evacuated. The soldier had no recurrence of elevated temperature and is making an uneventful recovery.

Case 2.—A soldier, admitted, Oct. 8, 1918, with a diagnosis of bronchopneumonia of all lobes of the right lung, in whose case, October 27, an additional diagnosis was made of acute cholecystitis and cholangeitis, developed a facial erysipelas, the following day, and remained in a very septic condition until November 23, when he was seen by a surgeon in consultation on account of pain in the left upper quadrant. There was dulness over the anterior portion of the left side of the chest in the mammary line just above the costal arch, and an obliteration of Traube's semilunar space. There was also very slight excursion of the left lower lobe into the costophrenic angle. There was also evidence of free fluid in the peritoneal cavity, but no rigidity or tenderness. Roentgenographic examination revealed a shadow in place of the normal gas bubble beneath the left dome of the diaphragm, and displacement of the heart toward the right. The right half of the diaphragm showed such a degree of elevation that a right subphrenic abscess was thought of; but on exploration with a needle, no pus was obtained. Pus, however, was obtained over the left lower chest in the anterior axillary line, and about 90 c.c. of chocolate colored pus were evacuated through an incision in the eighth interspace from the left subphrenic region. The symptoms of a generalized sepsis supervened, and the patient died a few days later. At necropsy the lower lobe of the right lung was found adherent to the diaphragm, and that of the left lung was covered with a thin yellowish exudate. Throughout the liver were scattered many small abscesses. A generalized peritonitis with 1,500 c.c. of free greenish yellow fluid confirmed the clinical diagnosis. The left subphrenic region was walled off, and the origin of the pus obtained at operation was seen to be from an extensive suppurative pylephlebitis. There had evidently been a direct infection of the left subphrenic region from rupture of one of the abscesses in the left lobe of the liver. The gallbladder and the appendix showed at this time no evidence of disease. A number of the mesenteric lymph nodes contained abscesses. A gram-negative bacillus which did not give the typical reaction of the colon group was obtained from the lungs, liver and peritoneum at necropsy.

JAUNDICE

The incidence of jaundice as seen postmortem has been about what one is accustomed to find in fatal cases of lobar pneumonia. Jaundice, in most cases with a marked discoloration of the skin and the mucous and serous membranes, has been present in 7 per cent. of 140 necropsies. In all except one, a bacteremia was demonstrable; *Streptococcus hemolyticus* was present in three, *Streptococcus viridans* in three, and pneumococcus Type IV in two cases. In only one case was there swelling of the ampulla of Vater. In this instance the mucous membrane of the gallbladder and the ducts was slightly swollen and inflamed, being most marked in the cystic duct. The swelling was not sufficient, however, to interfere with the free passage of bile to the duodenum. In all cases, the intestinal contents showed that bile was freely passing into the intestine, and stools examined during life gave no evidence of obstruction to the flow of bile.

SPLEEN

The spleen in the majority of cases was but very little enlarged. It was moderately firm on section and red. Microscopically a rather marked congestion was the predominating feature.

KIDNEY

Cases of true acute nephritis were extremely rare. Acute congestion of the kidneys was frequent. In one case, multiple abscesses of the kidney were a part of a hemolytic streptococcal septicemia, which had also caused a severe infection of one of the toes. Pyelitis demonstrated by ureteral catheterization was occasionally found.

Both renal and perirenal localization may be so severe as to endanger life, either during the stage in which some pulmonary condition is present, or independently of any other demonstrated focus, as is well illustrated in the following case of perirenal infection:

assumed a normal condition. She was instructed to return to the office at intervals of a week, or less time if necessary, for treatment, and was given a supply of lutein tablets to be taken in doses of 10 grains three times daily as long as required.

Subsequent injections of pollen extract (prepared in bulk) were given at the office: October 31, 0.01 mg.; November 4, 0.02 mg., at which time she exhibited a mild recrudescence of the rash on her face and neck, which she attributed to overexertion at her household duties and to indiscretion in diet; November 15, 0.02 mg.; November 20, 0.02 mg.; November 25, 0.04 mg.; December 3, 0.04 mg.; December 16, 0.04 mg.; January 6, 0.08 mg.; January 21, 0.12 mg.; February 28, 0.12 mg.

With the exception of a recurrence on November 4, the patient has been free from the skin eruption since leaving the hospital, although on two occasions she reported having experienced a slight stinging of the skin following unusual exertion. It has now been more than thirty days since the last injection was given, at which time she stated that in the future she would come for treatment only when she felt a recurrence of her symptoms. As she has not returned up to the present date, we may assume that the injections have afforded complete relief for a period of at least a month. Even more remarkable is the fact that she has been able to do all of her work, such as cooking, washing and housecleaning, and to eat some meat and other solid foods, which her condition had prohibited during the past year. She continues to take the ovarian extract and states that her periods are now regular and normal.

COMMENT

As to the permanence of results in this case, I am not prepared to say, as it might require quite an extended period of time, through the various seasons of the year, to determine all of the specific pollens to which the patient is sensitized. However, two conclusions may be advanced, namely: (1) that the basis of treatment of certain skin diseases with pollen extracts is scientific, being founded, as is bacterin therapy, on the theory of the production of antigens and antibodies, and should offer prospects of immunity or cure comparable to those of vaccines in general, and (2) that the immediate and complete relief afforded in the instance reported indicated a definite response to the injections of a foreign protein in the form of a pollen extract. If this method, by hypodermic injections at intervals varying from one to two weeks, proves applicable to other cases—which I see no reason to doubt, when a proper diagnosis is made—it is far preferable to the continuous ingestion and topical application of various medicinal remedies. I myself believe that when all of the specific pollens to which the individual is susceptible can be ascertained, this method of treatment offers the probability of relief and the possibility of a cure. If one can determine from the history of a patient, or from a botanical survey of his home surroundings the offending plants, an extract for both diagnostic and therapeutic use could be prepared.

I am now administering the spring pollen extract to a patient troubled with a rash apparently identical with that in the case reported, though milder, and after the first injection, she states that she has experienced decided relief. In all, she has received four injections, and since the last—now four days ago—the eruption has entirely disappeared, not returning even after perspiring, when the eruption would formerly always reappear. The size of the last dose was 10 c.c., representing 0.2 mg. of pollen protein-nitrogen, as she did not respond so readily to doses of 0.1, 0.05 and 0.02 mg. No results had been achieved by the previous administration of the fall extract in this case. This patient informs me that she has noticed that her skin is very sensitive to contact with tomato leaves, but as yet I have not applied the extract of this plant for diagnosis. She was, however, by the intradermic test susceptible to orchard grass, but was not susceptible to other spring and fall pollens.

The only negative phase I have observed after pollen extract injections was a slight headache.

ACQUIRED IMMUNITY TO INFLUENZA

AS INDICATED BY A RECURRENT EPIDEMIC IN AN INSTITUTION

JOHN H. HAMILTON, M.D.
Assistant Professor of Hygiene and Sanitation, State University of Iowa College of Medicine; Epidemiologist, Iowa State Board of Health
IOWA CITY

AND

A. H. LEONARD, M.D.
Physician, Training School for Girls
MITCHELLVILLE, IOWA

During the early part of November, 1918, there occurred an epidemic of influenza in the State Training School for Girls at Mitchellville, Iowa. At this time seventy-six of the girls had the disease. The second epidemic occurred in January.

The State Training School for Girls has approximately 180 students. They are housed in six cottages, about thirty girls residing in each cottage. By strict isolation, the epidemic was limited entirely to Cottages 2, 3 and 4. This epidemic subsided about November 15. From this time until January 6, the institution was entirely free from influenza. During this time there was in force rigid quarantine against the outside world.

It has for years been the practice of the institution to isolate in a detention hospital for two weeks all new arrivals. This practice has given the institution an enviable record so far as acute, infectious diseases are concerned.

One of the teachers in the institution was permitted to spend the week end of January 5-6 away from the institution. On the 6th and 7th she complained of feeling ill; she did not, however, go to bed, but continued her routine duties as teacher in the training school. This teacher lived in Cottage 6.

January 8, four students who were housed in Cottage 6 were sent from school sick. They had opportunity before being sent from school to disseminate the infectious agent to all students who attended school on that date. All the cottages of the institution were represented in the school in which these cases developed. Therefore all the families were theoretically equally exposed to the infectious agent.

Additional cases developed very quickly. January 10, twenty-nine cases were reported; the 11th, sixteen cases; the 12th, twelve cases; the 13th, six cases; the 14th, seven cases; the 15th, three cases; the 16th, three cases; the 19th, one case; the 23d, one case; total, eighty-two cases.

The distribution according to families was: Family 1, 16 cases; Family 2, 3; Family 3, none; Family 4, 2; Family 5, 33; Family 6, 28.

We see, therefore, that the epidemic is practically limited to the cottages that had escaped the ravages of the November epidemic. Of those girls who developed the disease in January, seven were recent arrivals, and two failed to develop the disease in November, although presumably exposed to the infectious agent at that time.

In the January epidemic there were few complications. Convalescence was much more rapid than in the first epidemic. Two patients developed otitis media. One of these had severe laryngitis. There were no fatalities following the January epidemic, whereas there were two deaths among the seventy-six cases that occurred in November.

The outstanding feature of the epidemic was the fact that those who had recovered from influenza were immune from a second attack of the disease. This evidence tends to prove that immunity to influenza can be acquired by having an attack of the disease, and that the duration of this acquired immunity is at least two months.

The students in this institution were all between 12 and 18 years of age. The fact that 158 out of 180 of these young people developed the disease also suggests that there is a small percentage, approximately 12 per cent., who are naturally immune to influenza.

THE ULTRAVIOLET RAYS IN THE TREATMENT OF CHILBLAIN

OSCAR L. LEVIN, M.D.
Instructor in Dermatology and Syphilology, New York Post-Graduate Medical School and Hospital
NEW YORK

Chilblain, or erythema pernio, is a form of erythema that appears in the late fall and winter months in individuals with a poor peripheral circulation and a disturbed vasomotor mechanism. In the mild cases there is merely a slight dusky or dark red discoloration of the regions with feeble peripheral circulation, as the tip of the nose, the lobes of the ears, the fingers, the toes, the heels and the cheeks. Usually, with the erythema, there is an exudation into the tissues resulting in the formation of papules, tubercles and plaques. In the severe cases, vesicles and bullae develop on top of the solid lesions. The vesicles, when ruptured or torn, give rise to erosions, ulcers and rarely to sloughing areas.

In the mildest cases there is no subjective symptom except discoloration of the skin. In the moderate and the severe cases the patients complain of mild, moderate or intense itching, burning or pain, and tenderness on pressure. The condition tends to run a prolonged course and is often rebellious to treatment. It persists at times for months until the beginning of warm weather. Then it disappears spontaneously, but with the coming of another winter it tends to return.

REPORT OF CASES

The winter of 1917-1918 was unusually severe. The number of patients with chilblain applying for treatment was consequently more numerous than in former years. The types of cases were often severe, persistent and obstinate in nature.

In one case which was particularly obstinate, after failing to obtain relief by the routine methods of treatment, I was led to try the ultraviolet rays as a therapeutic measure. The result was so gratifying that the rays were administered in two other cases with corresponding good results. It is therefore deemed justifiable to report these cases and to suggest this method of treatment for chilblain.

CASE 1.—A. B., a man, aged 25 years, a native of the United States, contracted syphilis in June, 1915, and had received since then regular antisyphilitic treatment. Because of his occupation he was constantly exposed to cold drafts and to frequent changes of atmospheric temperature. In November, 1917, he was attacked by severe chilblain. There developed rapidly on all the toes, the heels of both feet and the external surfaces of the feet, numerous purplish-red papules, tubercles and plaques, from the size of a small pea up to the size of a silver half dollar, surmounted by vesicles and erosions. Treatment failed to relieve or prevent the development of lesions, and the patient was compelled to stop work. One afternoon, each affected area was exposed for ten minutes to the ultraviolet rays emanating from a quartz, mercury vapor lamp, the quartz filter being placed at a distance of 10 inches from the skin. The next morning the pain and itching had ceased, and erosions showed a tendency to heal. At the end of a week all that remained of the condition was a slight, dusky discoloration. There has been no recurrence this winter.

CASE 2.—During the first week of December, 1917, N. R., a woman, aged 24, a clerk by occupation and a native of the United States, was referred by Dr. S. B. for treatment of dandruff and loss of hair from the scalp. Examination revealed besides the pityriasis steatodes of the scalp, evidence of anemia, hyperthyroidism, and a moderate form of erythema pernio of the dorsum of the fingers. The patient stated that chilblain had been present for two months and that she had had mild attacks during the two preceding winters. Her hands were exposed to the ultraviolet rays while the scalp was receiving treatment from the Heraeus sun lamp. After two ten-minute exposures, at a distance of 20 inches, administered at a weekly interval, there was a complete disappearance of the lesions.

CASE 3.—B. S., born in Russia, an unmarried woman, aged 22, referred for treatment by Dr. M. S., complained of a painful bluish-red eruption of the fingers of both hands, which she considered an infection subsequent to manicuring of the nails. The patient was well nourished but suffered from a poor vasomotor mechanism, as revealed by a marked dermatographia, excessive flushing, hyperhidrosis and a second degree erythema pernio of the dorsum of the fingers. The treatment advised in this case included a nonirritating diet, catharsis, iron and arsenic internally, massage of the fingers, and exposures to ultraviolet rays. Three exposures, each of ten minutes' duration and at weekly intervals, were administered. The pain was alleviated after the first séance, and the lesions disappeared after the third treatment.

COMMENT

The invisible ultraviolet and infra-red rays are to the right and left of the spectrum. The red and infra-red rays are heat producing and penetrating. The violet and ultraviolet rays produce a minimum of heat but possess marked chemical properties, are readily absorbed and are of value for therapeutic purposes. It has been shown that the therapeutic value of the sun is derived from the presence of the ultraviolet rays. Chilblain is essentially an erythema occurring in those with poor peripheral circulation and disturbed vasomotor tone. The good results obtained with the ultraviolet rays in this disease are probably due to the direct effect of the rays on the peripheral vessels and blood stream. It is therefore suggested that the rays be employed in the treatment of the condition, but not to the exclusion of other local and general measures. They are not only of value in removing the lesions, but if used sufficiently early in those who have had previous attacks they may prevent a recurrence.

161 East Seventy-Ninth Street.

BASAL-CELL EPITHELIOMA *

A. C. BRODERS, M.D.
ROCHESTER, MINN.

In the second of a series of articles on epithelioma published in 1918, MacCarty and I[1] classified such tumors into six types or apparent types and described each. The tumor commonly known as the rodent ulcer has been termed basal-cell epithelioma because its cells tend to differentiate to a form similar to the cells of the basal or germinative layer of the epidermis. This type, which, like other epitheliomas, may be found on any surface covered with protective epithelium, develops practically always above the clavicle. The majority of its lesions attack the cheek, the eyelids, the nose, the forehead, the ear, the canthi and the temporal regions.

Basal-cell epithelioma often appears in the skin as an elevated, whitish nodule which resembles an adenoma or cyst of a sebaceous gland, as an ulcer with indurated borders, or as a scaly lesion. The latter type, which exfoliates its superficial layers to a shiny surface but which shows little tendency to heal completely (Figs. 4, 5, 6, 7, 8 and 9), is usually found in persons who are exposed to intense sunlight. The cells of the basal-cell epithelioma vary greatly in morphology and in arrangement. They may be long and slender, short and thick, round, oval, or spindle shaped. In arrangement they may be alveolar or glandlike and resemble the structure of the thyroid; they may present a cactus-like appearance, a diffuse or circumscribed solid mass of cells, or a combination of these different types (Figs. 10, 11, 12, 13, 14, 15, 16 and 17).

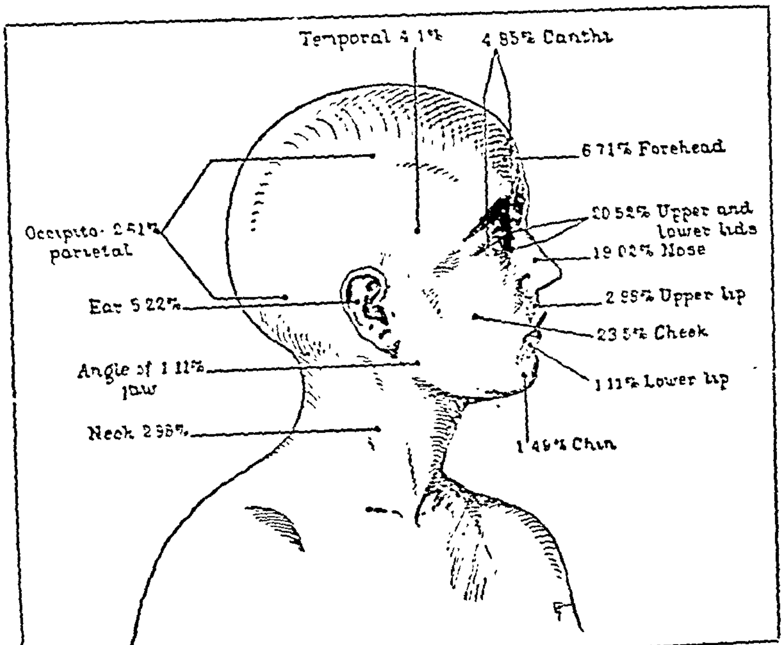

Fig. 1.—Location and percentage of basal-cell epitheliomas above the clavicle.

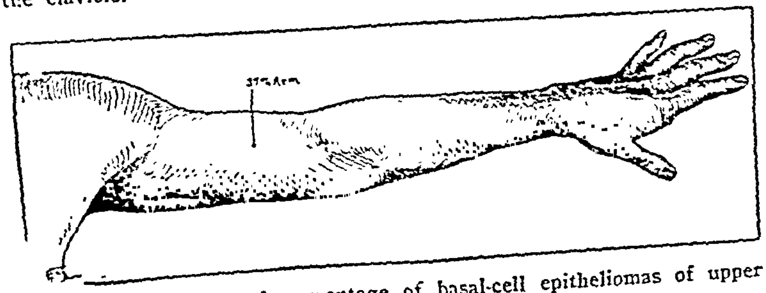

Fig. 3.—Location and percentage of basal-cell epitheliomas of upper extremity.

Since, as a matter of fact, all tumors arising in protective epithelium are basal-cell epitheliomas, their cellular differentiation is their only distinguishing feature. Because of some common characteristics, many basal-cell epitheliomas are undoubtedly diagnosed endotheliomas, alveolar sarcomas, round-cell sarcomas, spindle-cell sarcomas, and adenocarcinomas. Moreover, the cells of a pure basal-cell epithelioma are not supposed to contain prickles or spines; but because these do sometimes appear, it is often difficult to determine whether an epithelioma should be called a basal-cell or squamous-cell epithelioma, especially since prickle cells are found in so-called basal-cell epitheliomas, and basal cells can always be seen in squamous-cell epitheliomas. It now seems to be a well established fact that a basal-cell epithelioma can change into a squamous-cell epithelioma, or at least into an epithelioma in which the squamous cells predominate. We know, beyond a doubt, that basal cells and squamous cells may be shown intimately connected in a neoplasm (Fig. 18), and this may account

for the contention of some pathologists that basal cell epitheliomas do occasionally metastasize.

In the series of cases here reported, none have been included without a thorough microscopic examination. In distinguishing between cases that should be classified as basal-cell epithelioma and those that should be classified as squamous-cell epithelioma, the following rule has been adhered to: If the majority of the cells of the epithelioma are of the squamous-cell type, it is classified as a squamous-cell epithelioma; but if the majority are of the basal-cell type, it is classified as a basal-cell epithelioma.

There is, however, one tumor classified by some pathologists as a basal-cell epithelioma which is not included in these statistics: as we term it, a basal-cell-like epithelioma. This tumor occurs in the nose, in the pharynx, in the antrum of Highmore, in the parotid gland, in the cavity of the mouth, and in similar places. Although it is of long duration and has a microscopic structure similar to that of the basal-cell epithelioma, the trained eye will detect a difference; also, such tumors will metastasize, while the basal-cell epithelioma which occurs on the outer surface of the body is not supposed to do so.

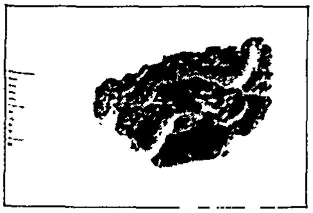

Fig. 6 (A 33173).—Basal-cell epithelioma of eyelid.

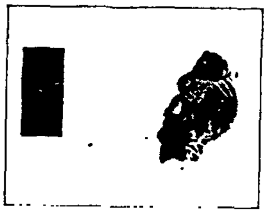

Fig. 7 (A 96196).—Basal-cell epithelioma of eyelid.

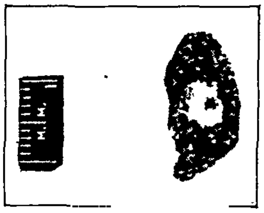

Fig. 8 (A 98228).—Basal-cell epithelioma of forehead.

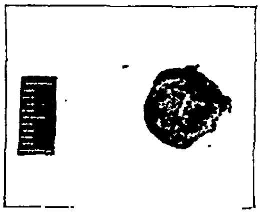

Fig. 9 (A 59758).—Basal-cell epithelioma of cheek.

In presenting this series of cases of basal-cell epithelioma, I have endeavored to classify the findings as briefly as possible, and, at the same time, to bring out the most important points. Its chief object is to present in tabulated form a collective history of the cases, so as to furnish data of the initial appearance, clinical manifestations, treatment, and ultimate fate of the basal-cell epithelioma. As the patients whose cases are tabulated here came to the Mayo Clinic between Nov. 1, 1904, and July 22, 1915, which period antedates the active use of radium

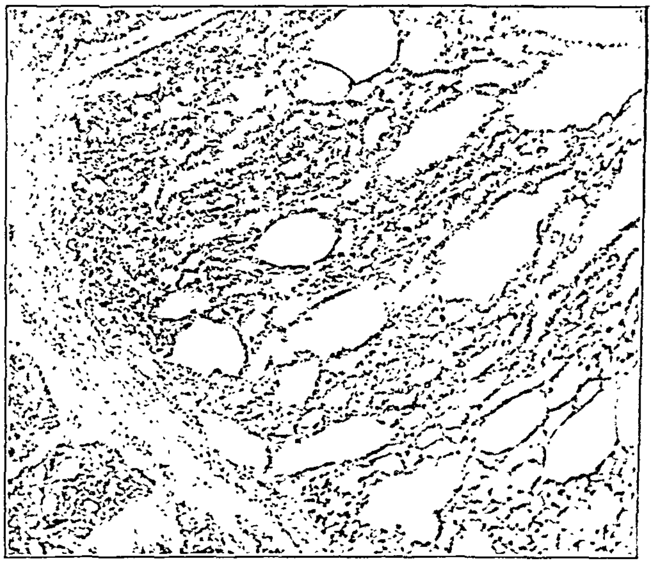

Fig. 10 (A 38151).—Basal-cell epithelioma of the outside of the nose. Note the close resemblance to thyroid.

in the treatment of this type of neoplasm, practically no account is given in this article of our experience with the curative properties of radium.

SUMMARY

1. Our present series of cases represents 13.4 per cent. of 2,000 cases of general epithelioma.

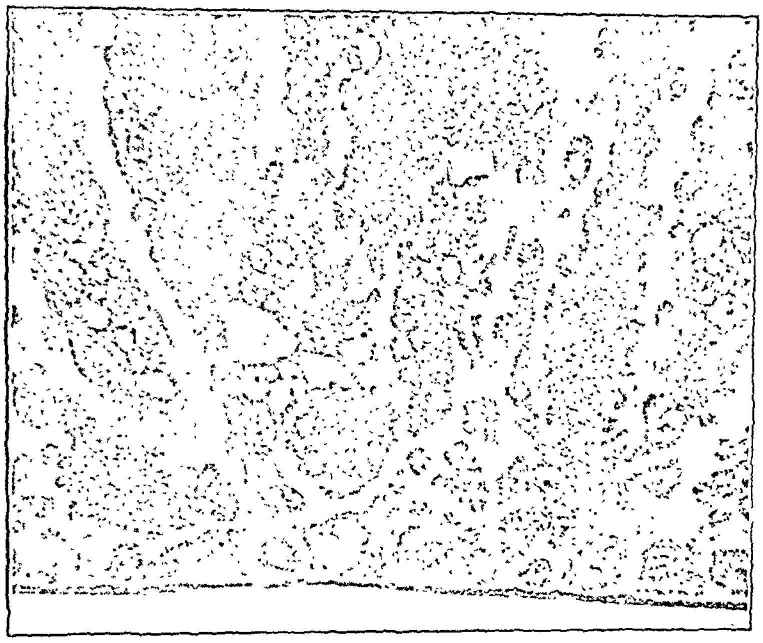

Fig. 11 (A 33009).—Basal-cell epithelioma of forehead, showing glandlike and solid areas.

2. Basal and squamous cells can be shown intimately connected in a neoplasm.

3. It seems to be a well-established fact that a basal-cell epithelioma can change into a squamous-cell epithelioma, or at least into an epithelioma in which the squamous cells predominate.

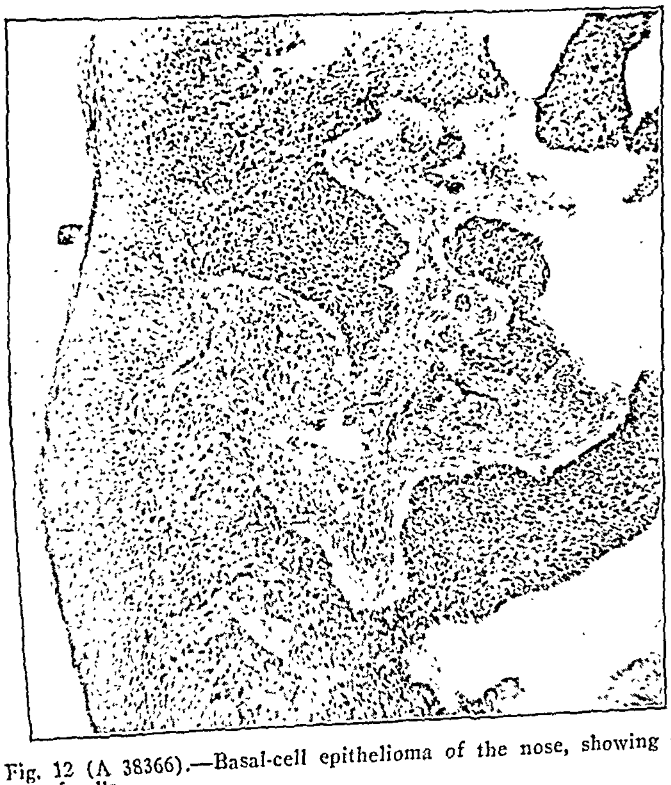

Fig. 12 (A 38366).—Basal-cell epithelioma of the nose, showing solid plugs of cells.

4. Basal-cell epithelioma occurs more often in males than in females, the proportion being about 3:2 in favor of the former.

5. The disease occurs in patients past middle life; their average age is 56.7 years.

6. It occurs more often in farmers than in any other class of people.

TABLE 4.—ULTIMATE RESULT

Fifteen (42.85 per cent.) of the 35 patients known to be dead were either operated on or treated with acids, carbon dioxid, etc., before entering the Mayo Clinic.

	No.
COMPLICATIONS IN THREE FATAL CASES	
Carcinoma of the breast	1
Carcinoma of the colon	1
Carcinoma of the body of the uterus	1

7. A family history of malignancy and a personal history of injury play a negligible part.

8. Previous mole, wart, pimple, eczema, scab, ulcer, etc., are associated in 37.1 per cent. of the cases.

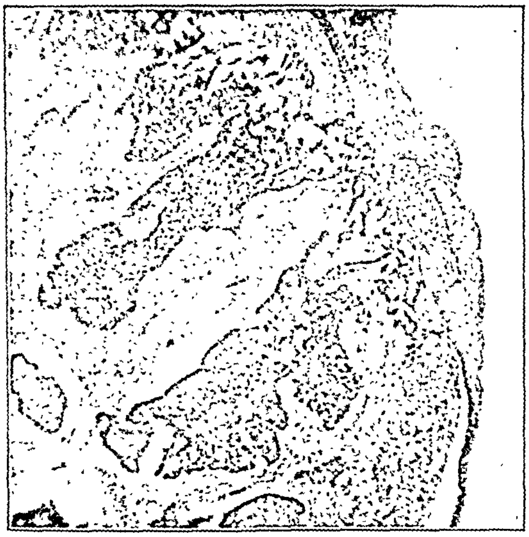

Fig. 13 (A 71769).—Basal-cell epithelioma of the cheek similar to Figure 11.

9. The duration of the lesion shows a marked variation; it extends from three months to forty-five years, and averages seven years and one month.

10. Ninety-six and twenty-eight hundredths per cent. of all the lesions occur above the clavicle.

11. Thirty-six and nineteen hundredths per cent. of all the patients had been either operated on or treated with acids, carbon dioxid, etc., before entering the Mayo Clinic.

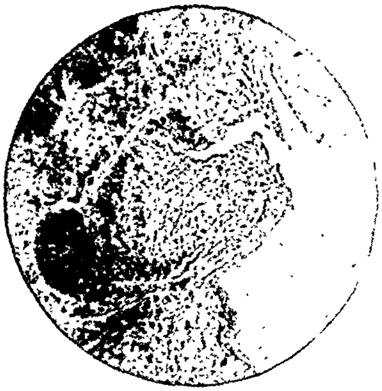

Fig. 15 (A 98228).—Basal-cell epithelioma of forehead; same as Figure 8.

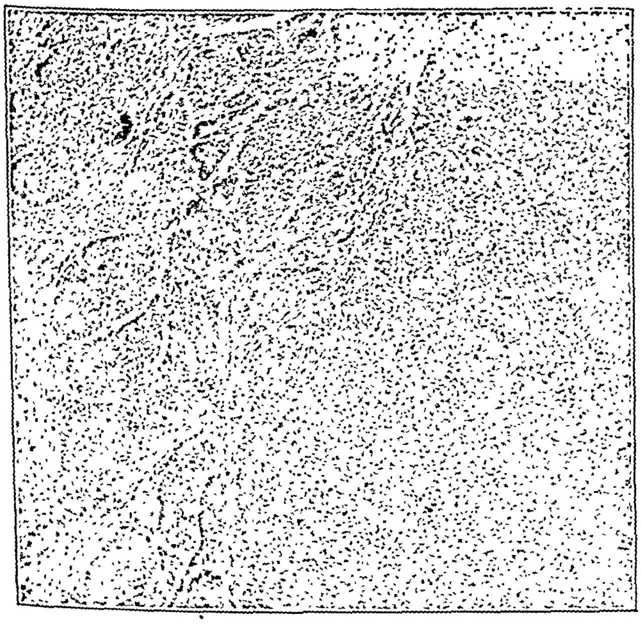

Fig. 14 (A 61661).—Basal-cell epithelioma of eyelid showing circumscribed and diffuse masses of cells.

12. In approximately 75 per cent. of all the cases treated at the clinic there was either one excision with the knife alone or one excision with the knife immediately followed by cautery.

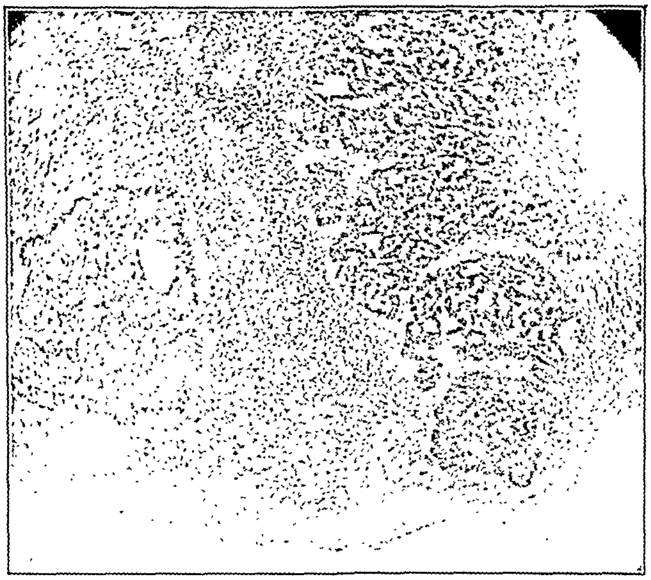

Fig. 16 (A 38151).—Basal-cell epithelioma of the outside of the nose, showing connection with epidermis; same as Figure 10.

13. Of the 54.1 per cent. of patients heard from, 75.86 per cent. are living, of whom 75.45 per cent. report a good result.

14. In the cases in which a good result was reported, 74.68 per cent. of the patients had either one excision with the knife alone or one excision with the knife immediately followed by cautery.

15. The patients treated with acids, carbon dioxid, etc., before entering the clinic did not get so good a result as those who had no previous treatment.

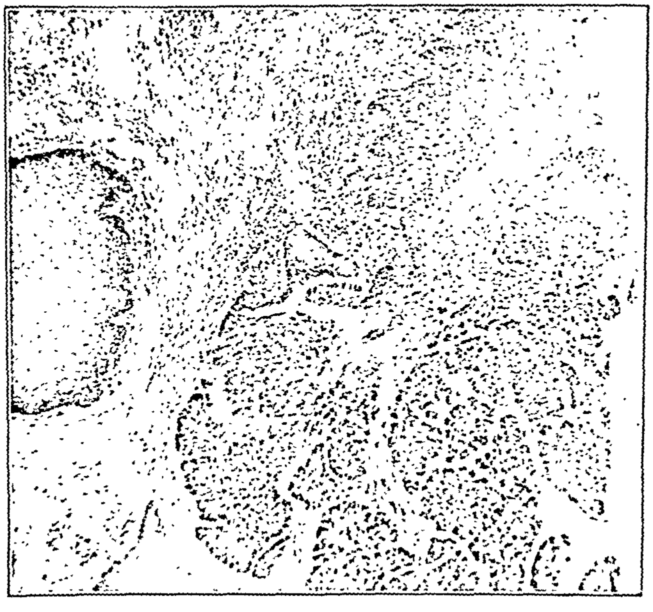

Fig. 17 (A 20310).—Gland type of basal-cell epithelioma of the outside of the nose, showing connection with epidermis.

16. The low [illegible]e of malignancy of the neoplasm is evidenced [illegible] long [illegible] lack of metastasis

in a single case in this series, response to proper surgical treatment, and by the fact that 75.45 per cent. of the patients reported living have been free from the disease on an average of six years, one and six-tenths months.

17. Of the patients reported dead, fewer than one third died from this disease.

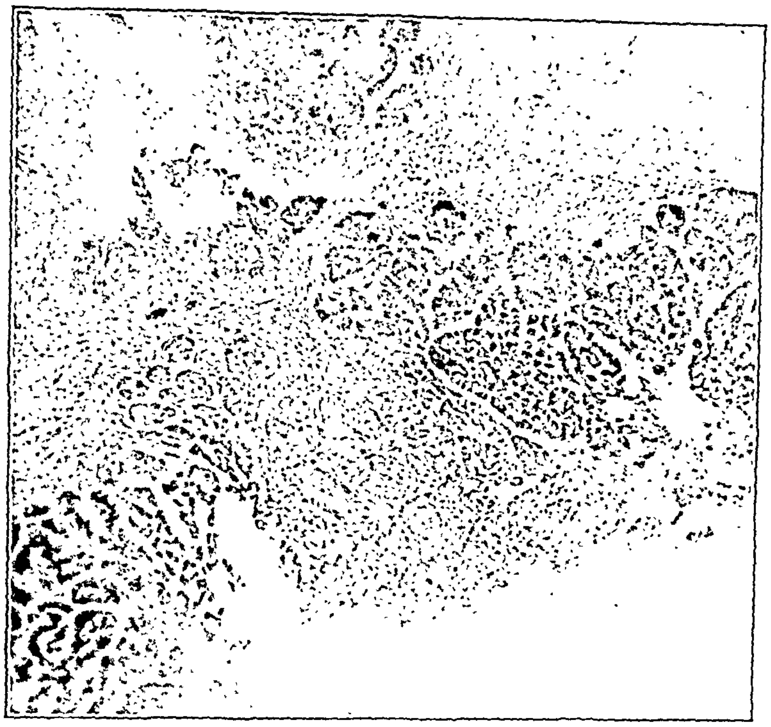

Fig. 18 (A 20310).—Gland type of basal cells intimately connected with squamous cells (typical metaplasia), adjacent to microscopic field of Figure 17.

18. Excessive exposure to sunlight as a cause of the neoplasm has not been borne out by the facts in our series of cases. It was noted that the hand, which is exposed to sunlight at least as much as any part of the body above the clavicles, did not show lesions.

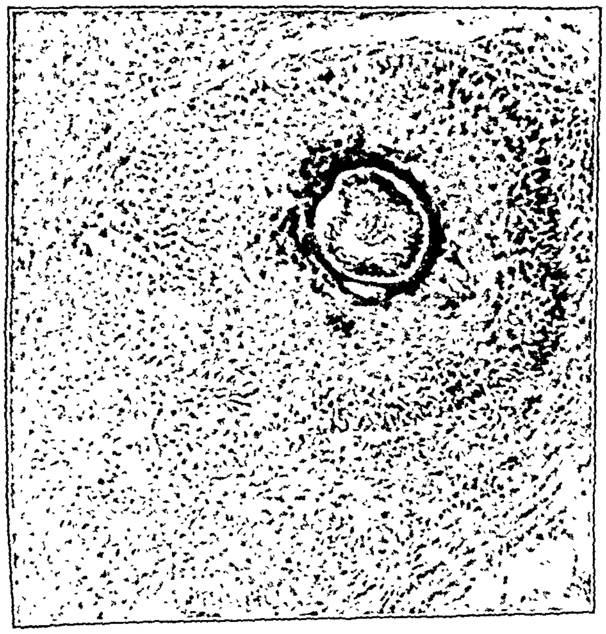

Fig. 19 (A 96196).—Basel-cell epithelioma of eyelid—originating from a hair follicle; same as Figure 7.

19. Practically all of the neoplasms in our series had their origin in the germinal layer of the epidermis of the skin. Only one was demonstrated to have originated from a hair follicle (Fig. 19).

TUBERCULOUS ANORECTAL FISTULAS

REPORT OF TWO CASES SHOWING SECONDARY LUNG INVOLVEMENT AND LATE CLINICAL EVIDENCE OF THEIR TRUE CHARACTER *

S. MORTIMER HILL, M.D.

AND

ARTHUR A. LANDSMAN, M.D.

Associates in Surgery of the Rectum, New York Post-Graduate Medical School and Hospital

NEW YORK

That abscess and fistula about the rectum are sometimes caused by infection with the tubercle bacillus is too well known to require more than passing mention, and, as the condition generally presents more or less definite clinical symptoms, its diagnosis does not offer any unusual difficulty, especially when there are corroborative signs in the lungs or other organs.

Briefly, a tuberculous fistula has an external opening that is patent, irregular and usually larger in size than that of the simple variety. It is more or less insensitive to probing and manipulation; discharges a thin, dirty gray material, seldom thick or creamy, and the skin surrounding it is bluish, undermined and unhealthy looking. The hair on the immediate neighboring parts is long, fine and silky; the buttocks are flattened, and the ischial tuberosities are prominent. While not all of these signs are present in every case, one or more of them are regularly in evidence very early in the disease, thus putting the surgeon on his guard in making his prognostic and therapeutic considerations.

Exceptionally we may meet some cases, however, in which they are doubtful, delayed or absent, in consequence of which it may not be recognized until late that we are dealing, not with a benign local infection, but with a serious general disease. In view of the obvious importance of these facts to all concerned, we desire to report two instances of this character that occurred in our experience during the past year:

REPORT OF CASES

Case 1.—M. S., a man, aged 49, a tailor, married, with negative family and previous history, developed one year before he came under observation a painful swelling about the anterior margin of the anus, which ruptured spontaneously and discharged a creamy liquid. Some weeks later he presented himself for treatment at the rectal clinic of the Post-Graduate Hospital, and was found to have a minute opening in the perineal skin, 2 cm. in front of the anus in the median line, which opened in the anterior wall of the anal canal, between the two sphincters. The tissues were sensitive to touch and probing, and the surrounding skin was pinkish and not undermined. There was no history of cough, hemoptysis, fever, gastro-intestinal disturbances or loss of weight, and examination detected no abnormal physical signs in the lungs or elsewhere. The case was therefore regarded as a simple, nonspecific anal fistula, and operation was performed under general anesthesia in the usual way. The patient was relieved of his pain and was lost sight of for a time. Later he again appeared at the clinic, some eight months after the onset of his symptoms, when his wound had grown considerably larger and looked rough, pitted, spongy and irregularly ulcerated, with its edges thickened and infiltrated. Tuberculosis was suspected and confirmed by laboratory examination of a piece of the excised tissue. The local condition improved, but the patient developed cough, dyspnea, and definite pulmonary signs.

* From the Department of Rectal Diseases, Post-Graduate Medical School and Hospital.

CASE 2.—C. J. O'N., a man, aged 40, an executive, married, with negative family and previous history, was taken ill one year ago with pain and swelling about the rectum, accompanied by constipation and general symptoms lasting several days. A diagnosis of ischiorectal abscess and fistula was made, and he was treated surgically; the wound showed no disposition to heal, and he was referred to the junior author, who found the opening of a small tract on the skin, 5 cm. from the anal rim, and to the left of it, which opened internally on the corresponding rectal wall, and showed no evidence, either in its physical condition or in its clinical characters, of signs other than those one would expect to find in a simple, nonspecific fistula. Neither was there a history of cough, loss of weight, or any abnormal findings in the chest. The patient was treated surgically and his wound improved for a time, but nine months after the onset of his trouble it is still unhealed, has assumed an unhealthy look, its edges are blue and undetermined, and the patient has a cough, positive sputum, and infiltration of both lungs.

SUMMARY

A summary of these two cases shows that they both began with what appeared to be an ordinary abscess and fistula about the rectum, persisted for a considerable time without showing any signs that would lead one to suspect their true nature, and were followed by pulmonary involvement. Without attempting to generalize from two cases, we cannot shut our eyes to the warnings that they carry:

1. Clinical signs that would serve to distinguish between specific and nonspecific local lesions about the rectum are not dependable, because they may be late in making their appearance; consequently, laboratory examination should be resorted to as early as possible.
2. There may be secondary pulmonary involvement from a tuberculous focus about the rectum, in individuals who lack resistance.

Dr. Wu Ting Fang on the Urgent Need of Public Health Work in China.—In his address to the missionaries at Canton in September, 1918, as set forth in the *National Medical Journal of China*, Dr. Wu Ting Fang, China's veteran statesman, in the course of a discussion on the public health needs in that country, said: "The work of public sanitation, which must be kept under a system of public inspection, should be undertaken by government agencies. China begins to realize the enormous toll in human life exacted as the price of ignorance in these matters. The elementary principles of sanitation and hygiene are violated constantly in our crowded cities. Ignorance of proper preventive measures exposes annually millions of our people to dangerous epidemic diseases, many of which, in the light of modern medical science, are considered preventable. China must organize against disease by promoting a nationwide campaign of enlightenment. A noteworthy feature of China's progress is the establishment of the National Medical Association of China, a purely Chinese organization of nearly one hundred Chinese physicians educated in western medical science and pledged to 'expedite the spread of modern medical science in China and to arouse interest in public health and preventive medicine among the people.'"

FRACTURE AND ORTHOPEDIC TABLE

ESPECIALLY DESIGNED TO AID IN THE TREATMENT OF FRACTURES, BY EITHER THE OPEN OR THE CLOSED METHOD

HUGH McKENNA, M.D.
Formerly Lieutenant-Colonel, M. C., U. S. Army; Chief of Surgical Service, U. S. Army General Hospital No. 22; President of the Staff of St. Joseph's Hospital
CHICAGO

Experience in surgery of bones and joints, particularly in the management of both the open and closed method of reducing fractures, led me to work out a mechanical device that would simplify this procedure.

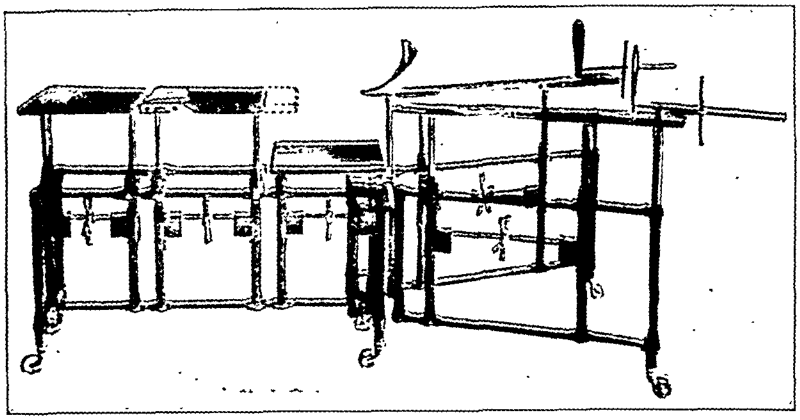

Fig. 1.—Table with lumbar segment lowered and the adjustable slide from the thoracic segment projected.

During the past year I presented my ideas on this subject to a hospital equipment manufacturer, and after submitting the drawings and a wooden model, the result of this effort was expressed in the fracture and orthopedic table herein described and illustrated.

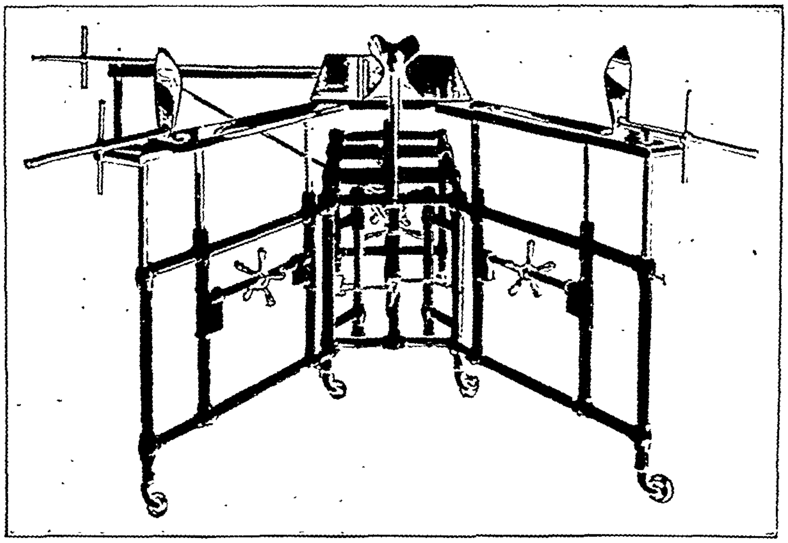

Fig. 2.—Table with leg segments divided.

War surgery has revealed lesions of so many parts of the anatomy that it was deemed advisable to construct an operating table that would permit of the maximum number of anatomic positions with the minimum degree of disturbance to the parts, in applying dressings and plaster-of-Paris casts, when the surgical procedure was completed.

The most difficult and distressing situation to be dealt with in bone and joint surgery comes in the treatment of these conditions in the lower extremities.

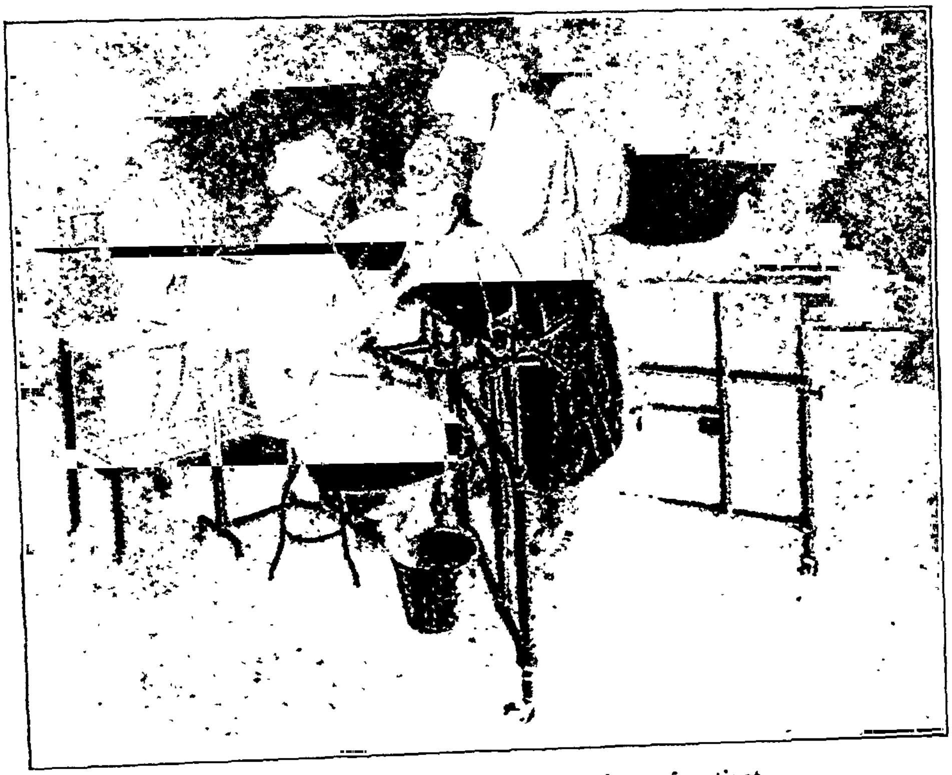

Fig. 3.—Assistant standing between legs of patient.

This led to the construction of an apparatus built on the principle of adjustable segments, which may be raised or lowered to any position desired by the surgeon.

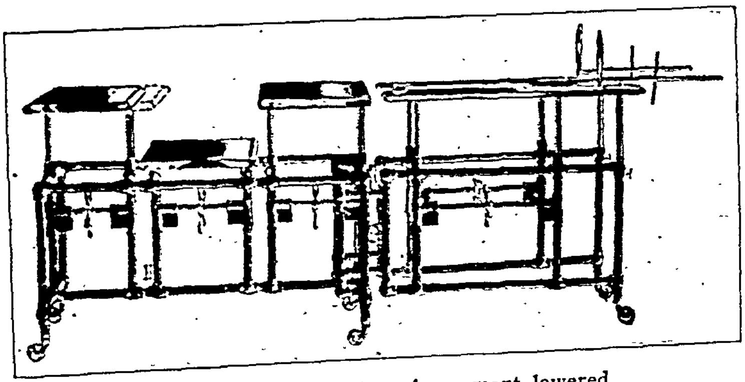

Fig. 4.—Table with thoracic segment lowered.

MECHANICAL CONSTRUCTION

The table is constructed on a segment or unit principle, which permits the units to be adjusted independently of one another.

By the lowering of one or more segments, the part to be operated on or dressed is not subjected to the same strain as would be caused if the same anatomic position were secured by elevation of the patient.

The same rigidity is secured with this construction, including the arm and leg segments, as is afforded by any single piece standard operating table, and at the same time the segments are adjusted with smoothness and ease. The segments, making up the table top, are raised and lowered by means of a spoked hand-wheel and steel shaft. These work in conjunction with a worm-gear and ratchet bar. The segment may be elevated or lowered as desired by a turn of the wheel.

This table presents an apparatus that renders it possible, by taking a position between the legs, for the operator to approach the inner side of the leg with the same ease as the outside.

Owing to the mechanical arrangement of the leg position of this table, the assistant is enabled to take a position between the legs where he can assist intelligently and with a relative degree of physical comfort, as shown in Figure 3.

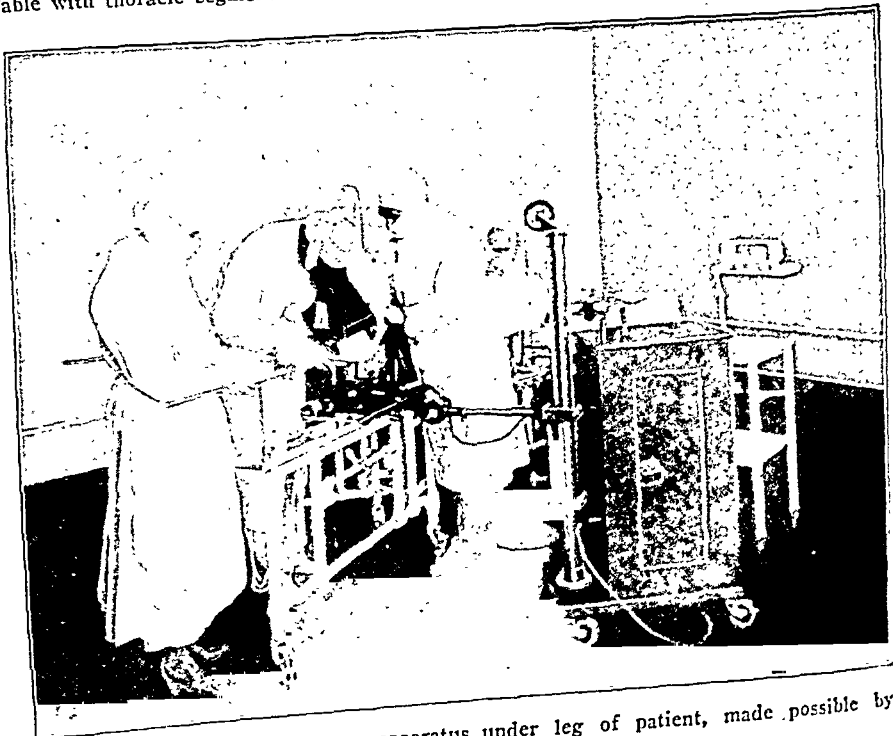

Fig. 5.—Portable roentgen-ray apparatus under leg of patient, made possible by dropping the right leg segment.

The leg segments, which can be lowered 9 inches, enable the surgeon to utilize a portable roentgen-ray apparatus in making a fluoroscopic examination of the bones and joints of the lower extremities. The same procedure may be carried out on the upper extremities by adjusting the arm segment. The parts may be presented in an admirable position for the application of surgical dressings or plaster-of-Paris casts. The bony segments may be held by this device with great precision after a fluoroscopic examination of a simple fracture or an open operation has enabled the surgeon properly to approximate the fractured ends of the bones.

By placing the patient on his abdomen, body casts may be applied by lowering the lumbar or thoracic segments. The latter positions will be found especially helpful in applying dressings in operations and in injuries to the spine.

ADVANTAGES

1. The table is constructed on the plan of segments so that the maximum number of anatomic positions may be presented for surgical operation or the application of dressings or plaster-of-Paris casts, with a minimum amount of disturbance during the procedure.
2. It is an apparatus for traction in reducing fractures either by the open or closed method. The completed table carries an adjustable slide for shortening or lengthening the lumbar segment to conform to the age or height of the patient.
3. The mechanical arrangement of the leg segments, which can be swung out at any angle, permits a division of the table so that the field of operation is as accessible on the inside of the leg as on the outside. This also permits what the designer claims is an advantage over any table now, to his knowledge, on the market, namely, the surgical assistant in hip and thigh operations, standing between the patient's legs, assists with more ease and skill than can be afforded in any other position.

PNEUMOCOCCUS TYPES IN RURAL DISTRICTS *

RUSSELL RICHARDSON, M.D.
PHILADELPHIA

Since Dochez and Gillespie[1] published their series of type determinations in cases of lobar pneumonia, much work of this character has been done. Almost all of the work, however, has been done in cases occurring in the cities, or, at least, in localities where contact would be a large factor.

In a series of cases covering four years at the Pennsylvania Hospital, Philadelphia, it appeared very noticeable that many of the Type IV cases presented a history of some exposure, which the patients considered to be the cause of their pneumonia. This was largely absent in the cases caused by the typical types. The latter, on the other hand, presented more frequently the history of a contact of some sort which would have given opportunity for inoculation with the infecting organism. The Type IV cases seemed to be largely due to a diminished resistance, while the typical types seemed to present a true contact infection.

DISTRIBUTION OF TYPES

Type	Number of Cases	Percentage	Average Percentage of Pennsylvania Hospital Cases
I	7	15.2	28.6
II	5	10.8	21.2
III	2	4.3	8.3
IV	32	69.6	41.8

Nichols,[2] working with pneumonia in the army, where, on account of the age and physical condition of the men, diminished resistance would not be expected, found 78 per cent. of all the cases caused by typical type organisms. The men in the army, living as they do in close association continually, afford the best possible opportunity for contact infection with the epidemic types.

It seemed that a study of the distribution of the types of pneumococci found in cases of pneumonia occurring in the country would be of interest. Here is lacking the personal contact with large numbers of people which is so distinctive a feature of life in a city. It was expected, for this reason, that the cases of pneumonia from the country might show a predominance of Type IV organisms.

The collection of sputum was accomplished by sending to a number of physicians, living in small towns and cities, containers with return label. The locations of the physicians was such that while the cases represented the typical patients from the country, yet they were not so far removed from the city that the sputum could not always be received at the laboratory in less than twenty-four hours by mail. In all, sixty-one specimens of sputum were received, and of these type determinations were made in forty-six. Some of those in which no pneumococci were found were not satisfactory specimens, and in some cases the original diagnosis of pneumonia was not confirmed by the physician's own further examination. In all of the forty-six cases there was apparently no question as to the diagnosis of lobar pneumonia.

The method for type determination was that used at the Hospital of the Rockefeller Institute. A few sputums which were apparently not properly collected and which appeared to be merely saliva from the mouth were disregarded.

The accompanying table shows the distribution of types.

It will be noticed here how much higher is the percentage of Type IV cases in the country than the average for four years in the city. In four of the Type I and in two of the Type II cases the patients had such an intimate contact with the city shortly before their pneumonia as to suggest the possibility of their having acquired the organisms there. Apparently without close contact between persons and the consequent chance to spread the infection, the typical types decrease until they cause only a small proportion of the cases of pneumonia.

New and Nonofficial Remedies

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application. W. A. Puckner, Secretary.

NEOARSPHENAMINE (See New and Nonofficial Remedies, 1919, p. 41).

Neoarsaminol.—A brand of neoarsphenamine.

Manufactured by the Takamine Laboratory, Inc., New York, under U. S. patent reissue No. 13,849 (Dec. 15, 1914; expires 1931) by license of the U. S. Federal Trade Commission.

Neoarsaminol, 0.15 Gm. Tubes.—Each hermetically sealed tube contains neoarsaminol 0.15 Gm.

Neoarsaminol, 0.3 Gm. Tubes.—Each hermetically sealed tube contains neoarsaminol 0.3 Gm.

Neoarsaminol, 0.45 Gm. Tubes.—Each hermetically sealed tube contains neoarsaminol 0.45 Gm.

Neoarsaminol, 0.6 Gm. Tubes.—Each hermetically sealed tube contains neoarsaminol 0.6 Gm.

Neoarsaminol, 0.75 Gm. Tubes.—Each hermetically sealed tube contains neoarsaminol 0.75 Gm.

Neoarsaminol, 0.9 Gm. Tubes.—Each hermetically sealed tube contains neoarsaminol 0.9 Gm.

MIXED BACTERIAL VACCINES (See New and Nonofficial Remedies, 1919, p. 296).

Swan-Myers Company, Indianapolis.

Swan's Mixed Acne Bacterin (No. 41).—Marketed in 6-Cc. vials, each cubic centimeter containing 25 million killed acne bacilli and 500 million killed *Staphylococcus pyogenes-albus.*

PERTUSSIS BACILLUS VACCINE (See New and Nonofficial Remedies, 1919, p. 287).

Swan-Myers Company, Indianapolis.

Swan's Pertussis Bacterin (No. 38) (Prophylactic).—Marketed in packages of three 1-Cc. vials, containing respectively 50, 100 and 200 million killed pertussis bacilli.

STAPHYLOCOCCUS VACCINES (See New and Nonofficial Remedies, 1919, p. 289).

Swan-Myers Company, Indianapolis.

Swan's Mixed Furunculosis Bacterin (No. 39).—Marketed in 6-Cc. vials, each cubic centimeter containing 500 million killed *Staphylococcus pyogenes-aureus* and 500 million killed *Staphylococcus pyogenes-albus.*

TYPHOID VACCINE (See New and Nonofficial Remedies, 1919, p. 292).

Swan-Myers Company, Indianapolis.

Swan's Typhoid-Paratyphoid Bacterin (No. 42) (Prophylactic).—Marketed in packages of three 1-Cc. vials, one vial containing 500 million killed typhoid bacilli and 250 million each of paratyphoid bacilli A and B, while the other two vials each contain 1 billion killed typhoid bacilli and 500 million each of paratyphoid bacilli A and B.

THE SYNTHETIC POWERS OF THE MAMMARY GLAND

The mammary gland has long been believed to be the seat of important synthetic activities. The casein, the sugar and to a lesser degree some of the fats of milk are different from any protein, carbohydrate or fat found elsewhere in the body. They have a specific character long recognized. What are the limits of the synthetic power of cells which can produce such distinct and specialized products? Can it produce them entirely de novo as the growing plant builds the most complex organic derivatives from very simple compounds, or is the synthetic capacity of the gland limited to a less profound sort of rearrangement of preformed fragments? It is well known in the case of the nutrition of growth that certain amino-acids are indispensable for the synthesis of tissue proteins. The capacity of the body to produce glycocoll seems to be almost unlimited. But without tryptophan or lysin new tissue cannot be formed; and unless they are supplied in some potential form in the diet, further synthetic progress is limited. Such is the evidence that the growing animal cannot manufacture all amino-acids with equal facility, if at all.

Is the highly specialized mammary gland more proficient than other groups of cells in the body? On the answer to this question depends the decision as to whether special dietary consideration must be given to the lactating individual. The problem has been excellently summarized by a group of investigators at the University of Wisconsin.[1] They remark:

> The mammary gland synthesizes a special sugar, as, for example lactose, but it probably starts with *d*-glucose, which as a precursor offers no unsurmountable difficulties. It makes a variety of fatty acids of special chemical character, but here again, whether originating from carbohydrates or preexisting fats, the chemical steps, at least theoretically, are capable of projecture. This gland makes a special protein, casein, and presumably from amino-acid fragments in the blood. It is also presumed that it makes casein, not through synthesis of amino-acids de novo, but by an orderly assembling, in quantitative relations, of those amino-acids found in the casein molecule. Should an amino-acid, occurring in casein and essential for growth, be absent in the diet, would there be a serious interference in casein building? Or does this gland retain special synthetic powers not shown by muscle cells, and in the absence of a specific amino-acid make it from other nitrogenous fragments?

The answer, in respect to the need of one amino-acid, lysin, the importance of which has been frequently emphasized of late, is furnished by the newest Wisconsin experiments. It is possible to prepare a diet free from proteins yielding lysin, yet adequate in every other respect. On such a ration, normal maintenance seems to be impossible; and judging by the fate of the young which suckle a mother dependent on a lysin-free diet, it appears very probable that the mammary gland cannot synthesize the missing amino-acid. For a time, milk production may proceed at the expense of lysin furnished by the breakdown of less essential tissues; but there is no evidence of reconstruction. As Hart, Nelson and Pitz[1] conclude, the evidence submitted supports the view that, so far as the proteins are concerned, milk secretion, like growth, is ultimately dependent on the quality and quantity of amino-acids ingested with the food. The lesson from this is clear. The importance of a properly selected diet, insuring an adequate supply of superior proteins, cannot be overlooked in the management of the lactating mother.

ARE ACID-FORMING DIETS DANGEROUS?

The remarkably effective way in which neutrality is regulated in the living organism has attracted attention from many standpoints in recent years. The regulation appears to be essentially physicochemical in nature, involving such a reaction between acids and bases that the hydrogen-ion concentration of the fluids bathing the tissues is practically constant. When it is recalled that our food intake, on the one hand, furnishes a variable mixture of acid and basic substances, while, on the other hand, the processes of metabolism may give rise to such acids as carbonic, lactic, sulphuric and phosphoric, as well as the base ammonia in addition to the potentially available supply of fixed alkalis, one can appreciate the careful adjustments of a chemical sort that must be made to secure a tissue medium of approximately constant reaction out of the variables that play on it. The acid components almost always preponderate; and accordingly there are several physiologic devices that assist in the removal of this excess. Carbonic acid is eliminated through the lungs, while fixed acids are excreted by the kidneys and sometimes, in lesser degree, by the bowel. Stores of alkali seem to be liberated automatically when they are needed to offset a surplus of acid that cannot be rendered inert in other ways.

Everyday experience shows that the normal fluctuating production of acid compounds—the natural end-products of an oxidative metabolism—are apparently taken care of with readiness by the ordinary processes of elimination and, in lesser degree, neutralization with ammonia. Clinical observations have established, furthermore, that when there is a defect in the eliminating mechanism, such as may appear in certain diseases of the kidneys, the neutrality regulation may be interfered with to a degree that upsets the usual equilibrium and gives rise to pathologic manifestations. To indicate this condition the much abused expression acidosis has sometimes been employed. The "alkali reserve" of the blood may be decreased.

---

[1] Hart, E. B.; Nelson, V. E., and Pitz, W.: Synthetic Capacity of the Mammary Gland, I, Can This Gland Synthetize Lysin? J. Biol. Chem. **36**: 291, 1918.

Lately the question as to whether the normal regulatory devices of the organism are adequate to meet the wide variations in reaction that are liable to be presented to it has been considerably debated. Not until the present decade has it been appreciated how extensively the preponderance of base-forming or acid-forming elements, respectively, in the diet may modify the disposal of acids from the body. Foods with a preponderance of acid-forming elements can increase the acidity and ammonia of the urine, and incidentally decrease its solvent power for uric acid. A reverse effect is brought about by liberal ingestion of base-forming foods. The outcome is not a question simply of the use of foods of animal or vegetable origin, respectively. Representatives of both sorts of reaction potentialities can easily be secured from either animal or plant sources. One may well ask whether more attention should not be paid to this intricate question of the influence of definite foods on the regulation of neutrality, since it is possible to modify it by diet quite as well as by the therapeutically familiar sodium bicarbonate. Sherman,[1] who has contributed important observations in this field from his laboratory at Columbia University, New York, has remarked that the benefit to health which so generally results from a free use of milk, vegetables and fruits in the diet may be attributable in part to the fact that these foods yield alkaline residues when oxidized in the body; but this point should not be too greatly emphasized, for there are several other respects in which the eating of liberal amounts of milk, vegetables and fruits is certainly beneficial, notably in supplying calcium, iron and vitamins, and in improving the intestinal conditions.

Clinical pathology has shown that the possibility of inadequate regulation may become a reality in disease. But are there unsuspected dangers of this sort associated with the nutrition of the healthy? Is it advisable to provide more carefully for the balancing of the potential acid and base of the ration? To cite a specific detrimental possibility, will a prolonged excess of acid-forming elements which might exist in natural foods exercise a deleterious effect on protein storage, such as growth and recuperation represent, by deflecting nitrogenous components to the production of ammonia for neutralization? Or will it drain needed fixed bases like calcium and the alkalis from the various tissues, to the detriment of the organism?

The experimental evidence respecting the protective devices of the body has long established the marked tolerance that exists for acid.[2] An exceedingly severe test has recently been contributed by Lamb and Evvard[3] of the Iowa Agricultural Experiment Station to the literature of the acid-base balance of the organism. They fed large and equivalent quantities of acetic, lactic and sulphuric acids, respectively, to growing swine. Those that received the inorganic acid which could not be oxidized further in the organism grew practically as well as the control lot. It seems established anew, therefore, that if the other elements in a natural ration are satisfactory, it is not necessary to balance the acid and basic mineral elements for growing swine. Presumably nutritional failures are often ascribed to excess acidity when other causes are not wholly excluded.

It is interesting to note how the large intake of sulphuric acid, amounting to 300 c.c. of normal acid in addition to that liberated through the body's metabolic processes, was disposed of. As much as three quarters of it was neutralized by means of ammonia. Extra urinary acidity accounted for another 5 or 10 per cent. The experiments also serve to allay the fears of those who suspect that an acid metabolism may rob the body of its calcium. Givens and Mendel[4] have demonstrated that neither acid nor alkali appears to exert any marked effect on calcium storage. The studies of Lamb and Evvard further demonstrated on a different species that mineral acid in large doses failed to cause a significant loss of calcium or interfere with the storage of protein.

The foregoing findings were ascertained by a study of the balance of the elements between the intake and output. Whether, under less normal conditions of diet, body damage may not result to tissues from prolonged "acidosis" in the course of time cannot yet be positively foretold. In a recent study of rabbits, Goto[5] examined the muscles and bones of animals that received a daily dosage of mineral acid. The results were not so conclusive as might be desired; yet the author believes them to indicate that next to the bicarbonates of the body fluids, the first major reserves of alkali drawn on in acid intoxication of rabbits are the alkali phosphates, particularly potassium phosphate, of the muscles, and the calcium carbonate of the bones. The bones do not lose calcium phosphate in appreciable amounts. What happens in clinical acidosis cannot yet be foretold.

EXPERIMENTAL POLYNEURITIS

It would be easy to give convincing illustrations of the enormous advantage that has accrued to the pursuit of the medical sciences from the ability to reproduce individual types of disease experimentally in animals. In the case of the infections, the nature of the etiologic agents has been established thereby. Rational therapeutics has received great help from the possibility of studying treatment in experimentally established disease. The so-called deficiency diseases afford a peculiarly characteristic illustration of the almost indispensable advantage of the ability to reproduce them at will. Birds, rats, mice, guinea-pigs and monkeys have shown typical and diverse susceptibilities to the lack of certain food factors in the diet. The cause, cure and prevention of such confusing maladies as beriberi, scurvy, pellagra and rickets in man seem destined to be more effectively understood as the result of the laboratory studies of the past decade than through the cruder, though by no means valueless, empiric observations of the preceding century.

Several of the more prominent human deficiency diseases, like those of infectious origin, seem to have found an analogue in symptoms that can be produced in certain species of animals under defined conditions. Just as not all of the animal forms are equally susceptible to tuberculosis or typhoid fever, for example, so the study of experimental scurvy has heretofore been confined to the guinea-pig and latterly also to the monkey, whereas beriberi has found its best experimental representation in the pigeon or the chicken. The experimental avian polyneuritis that can be induced by an exclusive diet of polished rice has unquestionably contributed much to the understanding of the etiology of beriberi and its prevention.

It is a further step in the direction of progress to be able to induce a comparable polyneuritis through selected deficient diets in the higher forms represented by the mammals. Thanks to the systematic efforts of Voegtlin and Lake[1] in the Hygienic Laboratory of the United States Public Health Service, a method has been evolved. Polyneuritis has been produced in cats and dogs as the result of an exclusive diet of lean beef which was heated for three hours at 120 C. in the presence of alkali (sodium carbonate). Proof of this statement is furnished by the symptomatology, treatment and pathology of the disease noted, which are essentially those characteristic of beriberi. The symptoms observed in these animals were diminution of appetite, constipation, loss of body weight, weakness and sometimes drowsiness, followed by paralytic symptoms, tonic convulsions, spasticity of certain groups of muscles, and disturbances of the circulation and respiration. The oral administration of active preparations of the antineuritic substance of yeast to paralyzed animals is followed promptly by the disappearance of the symptoms, and the continued administration of these preparations prevents the recurrence of the disease. In this respect there is an analogy, if not an identity, between the effects of yeast in preventing or curing polyneuritis and its favorable functioning as a "promoter of nutrition" by furnishing the indispensable water-soluble vitamin.[2]

In the case of these meat-fed animals, the inadequacy of the polyneuritis-producing diet is not attributable to a lack of the fat-soluble vitamin, such as is found in butter and egg yolk, or to a poor quality of proteins in the diet. The primary and principal fault must be associated with the destruction of antineuritic vitamin. Incidentally, it may be recalled that Osborne and Mendel have demonstrated that ordinary flesh (skeletal muscle) is at best poor in water-soluble vitamin.[3]

Fortunately, it appears from the government investigations that although high temperatures and alkaline reaction are a damaging combination for beef, it can be heated for three hours at 120 C. (248 F.) without completely losing its antineuritic properties. Voegtlin and Lake assume that the acid products, like lactic acid, present in flesh are responsible for the normal heat resistance of the antineuritic substance. Heating a food with alkali under pressure for considerable periods is rather drastic treatment from the culinary standpoint. Daniels and McClurg[4] have recently asserted, on the basis of their investigations at the University of Wisconsin, that heating even in alkaline reaction is by no means as destructive of the antineuritic properties of foods as has been alleged, particularly by McCollum. From a considerable experimental experience they regard it improbable that in the commercial canning of foods the vitamin is destroyed to such an extent that too little will be included in the diet when the usual amount of canned food is eaten. Even if there should be a considerable increase in the amount of canned food consumed, they believe that there will still be present enough of the antineuritic vitamin to meet the physiologic requirements, provided the diet is not materially changed in other respects. In the preparation of beef, in any event, for human consumption this food is rarely exposed throughout to a temperature exceeding 100 C. (212 F.). This procedure would seem to be within the danger limits of damage, so far as the antineuritic properties are concerned.

THE TISSUE FACTOR IN SHOCK

Few words now current in the medical sciences are likely to awaken so much confusion of ideas and uncertainty of judgment as is the expression "shock." It seems to represent a clinical entity of serious importance, in the interpretation of which all except the most critical students have run amuck. One after another the hypotheses to explain shock and the consequent suggestions for treating it have been martialed with a confidence seemingly born of exact knowledge —only to be shattered by conflicting evidence or before the approach of some more convincing theory. Meanwhile, keenly desirous of finding some solution to the serious and ever present problems of the clinical forms of shock, physicians have hastily grasped the current suggestions with eagerness that has been the forerunner of reluctance to abandon each pet theory. There is much sanity, therefore, in an appeal recently made by Dr. S. J. Meltzer[1] urging physiologists, when they undertake to apply their scientifically trained minds to problems of the practice of medicine, to adhere firmly to the careful, critical methods that they are in the habit of employing in their physiologic researches. This he urges, although recognizing that the actual yield to medicine as a consequence may be slow and, perhaps, even small. He also reminded clinical men to imbibe well-established new physiologic facts, but in the application of these facts to stick closely to well-established, careful clinical methods.

Profiting by such warnings, we shall not venture any offhand pronouncements in explanation of shock. But as progress can be initiated only by new observations and renewed discussion, attention is called to an aspect of the question that has only recently begun to attain recognition, namely, the nutritional disturbances that may be an underlying factor. Shock has long been looked on essentially as a circulatory upset. The "primary" shock often comes about so promptly after an injury as to be explained quite naturally as a result of nervous action. It is well known that a condition resembling shock in greater or lesser degree can be induced experimentally by numerous procedures, including mechanical injuries, hemorrhage, overanesthesia, or interference with the blood supply to a part. The more recent point of view has been well summarized by Gesell.[2]

In his research, Gesell considers shock in a very general way as a combined circulatory and nutritional disturbance resulting from a number of forms of tissue abuse which, if left to run their course, may lead to death. Even though these forms of tissue abuse, the initiating causes, may be removed, the fatal issue is not necessarily avoided. Gesell adds that some changes apparently have taken place as a result of the tissue abuse which sustain the condition. The factors in shock are therefore divided into initiating factors and sustaining factors. The initiating factors, says Gesell, ultimately lead to changes in the tissues which have their influence on the "sum of the processes concerned in maintenance and repair" of living tissue. There are cellular damage, increased permeability of cells, transudation, eventual decrease in blood volume, slowing of the blood stream, etc. These represent sustaining factors, some of which are not readily removed.

The analysis of this condition, if in any degree correct, must serve to direct attention away from some of the factors, such as mean blood pressure, that have hitherto been too exclusively made the center of consideration. It is scarcely necessary to recall that the modes of combating surgical shock by injecting drugs intended to raise blood pressure have not been found adequate. Despite an increased blood pressure, the "nutrient flow" to the tissues may be entirely unsatisfactory. They may become damaged. The injury may be chemical in origin and may produce transudation of plasma and stasis of blood. As Gesell pictures this aspect of the problem, the decreased blood volume, eliciting a vascular constriction, reduces the flow of blood to a level below that essential for normal nutrition and far below that essential for deteriorated tissues. The condition is thus sustained by the disturbed nutrition and by the consequent inability on the part of the animal to recover the normal permeability of the vessels and therefore restore the normal blood volume that is so essential for an adequate flow of blood. Since the circulatory and nutritional disturbances are so closely interdependent, one disturbance may become as important as the other.

If the diverse schemes for transfusion, including the use of blood and of alkaline and viscid solutions, have not succeeded in meeting the needs of the damaged tissues, it becomes a problem of the future to recognize the impending circulatory changes before they can do serious damage to the tissues by depriving the latter of proper nutrition. It will further be necessary to devise additional methods to provide damaged tissues with a suitable circulating medium and to combat the abnormal permeability of some of the peripheral vessels. In other words, chemical and nutritional factors as well as nervous and circulatory forces must be taken into consideration in making an adequate study of shock.

Current Comment

MODERN HEALTH ORGANIZATION IN NEW MEXICO

Congratulations to New Mexico, the last one of our states to establish some form of organized state public health machinery. In his report on state public health work, made five years ago, Dr. Chapin said of New Mexico, "It is unfortunate that a state with a population which now probably numbers nearly half a million should do nothing whatever for public health. It is the only state of which this can be said." Happily, this is no longer true. March 14, the bill proposed by the New Mexico Public Health Association passed the senate unanimously. It had already been adopted by the house. The bill provides for a board of three members, one of whom may be a physician. The health commissioner must be a "person having experience and special training in sanitary science and public health administration." His salary is fixed at $3,000. A long list of functions of the state board are enumerated in the measure, among them being power to investigate and control diseases; inspect public buildings, private premises and industries; establish, maintain and enforce quarantine; collect, compile and tabulate reports of marriages, births, deaths and morbidity; disseminate public health information; prevent infant mortality; promote child hygiene; regulate the sanitation and safety for consumption of milk, meats and other foods, and supervise the work of local health authorities. An appropriation of $20,000 is made for the first year. As the last state in the Union to adopt modern public health legislation, New Mexico has been in a position to profit by the experience and mistakes of her sister states. The incorporation in a single public health law of provisions for vital statistics, infant mortality, child hygiene, food control, and supervision of local public health authorities is to be highly commended. The amount appropriated is, of course, too small for a completely organized and equipped state health department; but if the funds available are wisely expended, the people of New Mexico will soon realize that money spent for public health is one of the best investments that the people of the state can make, and will support the new board by larger appropriations. The organization and development of state health activities in New Mexico will be watched with great interest.

NEEDS OF MEDICAL EDUCATION AS REVEALED BY THE WAR

The world war has called attention to special needs in every line of human endeavor. No previous war had so involved the entire world or so hazarded the very existence of practically every civilized government. In no previous war was such extensive use made of those who had reached the highest attainments of human skill and ingenuity. The urgency and extent of this demand naturally drew attention to the scarcity of those who were qualified to render service along highly technical or specialized lines. So in medicine there was an unprecedented demand for physicians of exceptional qualifications and skill in the various specialties, such as pathologists, bacteriologists, psychiatrists, and, of course, expert surgeons along special lines, as, for instance, brain surgery. Here, likewise, the urgency of the demand has forcibly revealed the fact that the supply of physicians having such skill is comparatively limited. This revelation, however, does not call for a violent condemnation of medical education of the past, but does lay special emphasis on the possibilities and aims of medical education in the future. As a matter of fact, the improvements of the last fifteen years have been directly in line with these needs and are, therefore, a matter of congratulation. The United States was never so well supplied with physicians who were as thoroughly trained or as skilled in the specialties, as at the time it entered the world war. Meanwhile, the war has rendered a great service in revealing the possibilities and benefits that will result from higher attainments in medicine. This shows the necessity of continuing the campaign for improvements, not only in undergraduate but also in graduate medical education. If the highest attainments are of such vital importance in great national crises, how much greater will be the service to the public whether there be peace or war.

THE VIRTUES OF OMISSION

In a recent issue of a publication devoted to advertisers, the Cleveland *Plain Dealer* carried a full-page advertisement to give publicity to the fact that "on seventeen important lines of business" it had carried more advertising during 1918 than any other paper in the same city. The seventeen different kinds of business were named and tabulated, ranging from Autos, Books and Stationery, through Electrical and Financial, Railroads and Steamships, to Schools and Colleges. Not a word in the advertisement was said about medical advertising. Possibly the *Plain Dealer* does not carry any, although it is morally certain that it could get all it wanted, for every reputable newspaper is offered more "patent medicine" advertising than it will accept. The significant facts are that either the *Plain Dealer* doesn't cater to medical advertising, or if it does, it makes no effort to give publicity to the amount it gets. That no reputable newspaper ever brags about its desirability as an advertising medium for medical "copy" speaks volumes for the ethical and moral status of the "patent medicine" business.

Winter Hibernation of Mosquito Larvae.—Asst. Epidemiologist T. H. D. Griffiths of the United States Public Health Service in *Public Health Reports,* Nov. 15, 1918, gives the results of his search for mosquito larvae after the advent of cold weather and summarizes the results as follows: Anopheles (*crucians* and *punctipennis,* at least) pass the winter in the larval stage. This is true for northern Louisiana (for *crucians*) during a severe winter for that section. Evidence, though less conclusive, shows that *A. punctipennis,* at least in the larval stage, withstands a severe eastern Virginia winter. Apparently pupation does not occur at low temperature, or until ordinary room temperature obtains. In selected places considerable numbers of anopheles larvae pass the winter as such.

Association News

HOTEL HEADQUARTERS AT ATLANTIC CITY

The Local Committee on Arrangements announces the following as the hotel headquarters for the coming annual session of the American Medical Association to be held in Atlantic City, June 9-13:

General Headquarters	Marlborough-Blenheim
Practice of Medicine	Dennis
Surgery, General and Abdominal	Chalfonte-Haddon Hall
Obstetrics, Gynecology and Abdominal Surgery	Breakers
Ophthalmology	Traymore
Laryngology, Otology and Rhinology	Chelsea
Diseases of Children	Seaside
Pharmacology and Therapeutics	Arlington
Pathology and Physiology	Royal Palace
Stomatology	Craig Hall
Nervous and Mental Diseases	Brighton
Dermatology	Blackstone
Preventive Medicine and Public Health	Shelburne
Genito-Urinary Diseases	Alamac
Orthopedic Surgery	St. Charles
Gastro-Enterology and Proctology	Bothwell

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending March 14, the Medical Corps contained 20,679 officers, a decrease of 153 from the previous week. The Medical Reserve Corps contained 1,029 officers. The total number of medical officers discharged since the beginning of the war is 12,742.

Medical Veterans of the World War

Forms for applying for membership in the Medical Veterans of the World War, as well as copies of the constitution of that organization, may be obtained from the secretary, Col. F. F. Russell, M. C., U. S. Army, Army Medical School, Washington, D. C. Copies also may be obtained from the headquarters of the American Medical Association; send stamped addressed envelope.

Military Cross Awards

The following medical officers have been awarded the military cross for bravery and distinguished service in action: Irving F. Barnett, Captain, M. C., U. S. Army, Chicago, and Earl R. Chamness, Chicago, Griffith A. Demay, Indianola, Neb., James W. Aldridge, Covington, Ind., William H. Caine, Willoughby, Ohio, Oscar H. Peterson, Lamoni, Iowa, Paul J. Preston, Minneapolis, and George H. Reddick, Wabeno, Wis., Lieutenants, M. C., U .S. Army.

Personal

The President, before his departure for France, March 5, made recess appointments of Walter D. McCaw, Col., M. C., U. S. Army, and Robert E. Noble, Lieut.-Col., M. C., U. S. Army (temporary Major-Gen., M. C., U. S. Army), to be permanent brigadier-generals of that branch to fill the two vacancies created by the act of Congress of July 9, 1918.——Officers of the hospital division of the Surgeon-General's Office tendered a farewell dinner, March 6, to the chief of that division, Winford H. Smith, Col., M. C., U. S. Army, Baltimore, who was retired as chief of the division, and Louis B. Baldwin, Lieut.-Col., M. C., U. S. Army, Minneapolis, in charge of administration of hospitals in the division.——By conference agreement, promotion in the retired list from colonel to brigadier-general has been provided for L. Mervin Maus, Col., M. C., U. S. Army. The Senate had previously passed a separate bill to authorize the rank of brigadier-general for Colonel Maus.

Wounded Slightly

The following officers are reported in the Official Bulletin to have been slightly wounded: Harrison J. McGhee, Major, M. C., U. S. Army, Morrisdale. Pa.; William Gramley, Franklin, Pa., Norman Oscar Nelson, Baltimore, and Leslie C. Russell, Newark, N. J., Captains, M. C., U. S. Army, and Wiles H. Allen, Atlanta, Ga., Bret Verne Bates, Wheaton, Minn., Alfred E. Kinney, Astoria, Ore., John Edward Newhouse, Wilkinsburg, Pa., E. Roger Samuel, Mount Carmel, Pa., Warde Byron Smith, Frankfort, Ohio, and William Westrate, Zeeland, Mich., Lieutenants, M. C., U. S. Army.

Red Cross President Goes to France

Dr. Livingston Farrand, the new chairman of the central committee of the American Red Cross, sailed for France on March 9. He has gone abroad to study the problems of the organization in Europe and to confer with Henry P. Davison, now a member of the executive committee and formerly chairman of the war council, on the international conference of the Red Cross societies called to meet at Geneva thirty days after the declaration of peace. In France he will be joined by a number of American health experts and men from the other allied countries. He will remain abroad until the latter part of April.

Volunteer Medical Service Corps to Be Disbanded

The press reports that the Volunteer Medical Service Corps is to be dissolved on April 1. The list of members in the corps, it is understood, will be turned over to the Public Health Service.

Wounded Severely

The following officers are reported in the Official Bulletin as having been wounded severely: Lomax Gwathmey, Major, M. C., U. S. Army, Norfolk, Va.; Gail K. Butt, Johnstown, Ohio, Edgar R. Hiatt, Portland, Ind., and Walter Harvey Kirkpatrick, Hutchinson, Kan., Lieutenants, M. C., U. S. Army.

Prisoner Released

The following officer who has been prisoner in Germany, is reported to have been released and returned to France: John Steele Abbott, Lieut., M. C., U. S. Army, St. Paul, Minn.

Hospitals Abandoned

The War Department announces that U. S. General Hospital, Long Beach, N. Y., and U. S. General Hospital No. 35, West Baden, Ind., will be abandoned in the very near future. The commanding officer of the hospital at Long Beach has been directed to transfer all patients and dispose of personnel as rapidly as possible in order that salvage and restoration proceedings may start, March 15. General Hospital No. 35 is to be abandoned on June 30, at the expiration of the present lease and no patients are to be sent to this institution after May 1.

Distinguished Service Cross Award

The Commander-in-Chief, in the name of the President, has awarded the Distinguished Service Cross to Elam F. Srygley, Lieutenant, M. C., U. S. Army, Fourth Machine Gun Battalion, Greystone Park, N. J.

"For extraordinary heroism in action near Medeah Ferme, France, Oct. 8 to 9, 1918. When a platoon was being heavily gassed and under intense artillery and machine-gun fire, Lieutenant Srygley voluntarily left the shelter of his dressing station, proceeded to the line, and rendered invaluable aid to the wounded. On October 9, Lieutenant Srygley again left the shelter of his dressinig station, and under intense fire voluntarily went to the assistance of the wounded of the 141st Infantry."

Wounded, Degree Undetermined

The following officers are reported in the Official Bulletin as having been wounded (degree undetermined): Charles H. Mielke, Kansas City, Kan., and Frank C. Robinson, Martinsville, Ind., Majors, M. C., U. S. Army; Robert E. Walsh, Captain, M. C., U. S. Army, New York, and Robert H. Breslin, Providence, R. I., William A. Brewer, Memphis, Tenn., William A. R. Chapin, Springfield, Mass., Lacy W. Corbett, Bishopville, S. C., James S. McNett, Endicott, N. Y., Julius Pincus, Brooklyn, N. Y., Joseph E. Rapuzzi, Ithaca, N. Y., Joseph Armin Stackhouse. Ambler, Pa., and Orlyn Wiseman, Pedro, Ohio, Lieut [illegible] C., U. [illegible] Army.

Army Medical Boards Appointed.—Surgeon-General Ireland has appointed a Board of Medical Officers to take the subject under consideration and to make recommendations regarding the reorganization and the equipment on a peace basis, of Red Cross Base Hospitals. This board consists of Brig.-Gen. Francis A. C. Winter and Cols. Paul F. Straub and Robert U. Pattison. The surgeon-general has also appointed a board of medical officers to consider and make recommendations based on reports of medical officers concerning their experiences during the war. The latter board is comprised of Brig.-Gens. Francis A. Winter and John M. T. Finney and Col. Lewis A. Conner. All these except General Finney and Colonel Conner are members of the old Regular Army Medical Corps.

Results of Mental Tests at Camp Grant

According to a report by Lieut.-Col. George B. Lake, camp surgeon at Camp Grant, the results of the psychologic tests among the officers and men in the camp showed that the members of the Medical Corps rank lower than commissioned officers in any other branch of the service. Officers of the Quartermaster's Corps were rated highest, with an average of 147 points out of a possible 212 in the "Alpha" test. Infantry officers ranked second, with an average of 141.8 points while the Medical Corps was third, with an average of 138.6 points. Sixteen hundred officers were examined of whom 180 were from the Medical Corps. Only one soldier of the 90,000 taking the tests at the camp made 200 points out of a possible 212; seven made from 190 to 199. The showing among the noncoms and enlisted men is materially lower than that of the officers, the record among the enlisted men being made by those at the base hospital.

Praise for Naval Medical Officers

General John A. LeJeune, U. S. M. C., writing unofficially from the headquarters at Heddesdorf, Germany, to Rear Admiral William C. Braisted pays a high tribute to the officers of the Medical Corps of the Navy, and Naval Hospital Corps who served with the Second Division in France. He says:

> "The officers and men who served with the marine brigade cannot be commended too highly. Many of them received distinguished service crosses and many received the Croix de Guerre, and many more were recommended for crosses. * * *
>
> "*I desire especially to mention* Lieutenant Commander Boone. He is my ideal of what a medical officer should be. He is brave as a lion, untiring and self-sacrificing to an extraordinary degree, and a man of great ability and of the soundest judgment. He gave himself completely to his duty, and all of his thoughts were of the sick and wounded. He wore himself out and had to go to the hospital in December. It was an inspiration to be associated with such men as he and Lieutenant-Colonel Derby, the Division surgeon. Boone needs a good long rest. We cannot afford to lose him."

Difference in Pay Not Allowed

Paul Kurt Sauer, Lieut., M. C., U. S. Army, on duty at U. S. General Hospital No. 21, Carlisle, Pa., was denied a claim of difference of pay for exercising higher command from Oct. 3, 1917, to March 3, 1918. In denying the claim the comptroller says: "To entitle an officer to additional pay under Section 7, of the Act of April 26, 1898, for exercising in time of war 'a command above that pertaining to his grade' he must have been 'serving with troops operating against an enemy' and exercising such a command 'under assignment in orders issued by competent authority'. The term 'command,' as used in the statute, means an organization of troops. If the company to which an officer was assigned was a provisional company for training purposes only, and did not constitute a part of the normal organization of the Army, payment of the higher grade is not authorized. The service for which additional pay is claimed was rendered at Camp Funston, Kan. It does not appear that the claimant was exercising a higher command under any assignment in orders issued by competent authority, and it does not appear that he was serving with troops operating against an enemy."

Cited in Orders

The following medical officers attached to the Ninth Infantry Brigade, American Expeditionary Forces, were cited in orders, Dec. 31, 1918, for distinguished conduct in action:

HAROLD H. GOLDING, Lieut., M. C., U. S. Army, Sixty-First Infantry. For distinguished service while in action at Cunel, Oct. 14, 1918. Lieutenant Golding showed absolute disregard for personal safety while caring for and dressing wounded, under constant shell fire.

FRANK A. MOOSE, Lieut., M. C., U. S. Army, 61st Infantry. For distinguished service while in action in Bois-de-Foret near Farm-de-la-Madeline, Oct. 13, 1918. Lieutenant Moose showed absolute disregard for personal safety while caring for and dressing wounded under heavy shell fire, until the field was entirely cleared of the wounded, and remained after the battalion had been relieved for half an hour.

EDWARD H. TONELLE, Lieut. M. C., U. S. Army Detachment, 61st Infantry. For distinguished service while in action at Cunel, Oct. 14, 1918. Lieutenant Tonelle showed absolute disregard for personal safety while caring for and dressing wounded, under constant shell fire.

Charles T. Maxwell, Capt., M. C., U. S. Army, Sioux City, Iowa, has been twice cited for bravery, *the second time* for going through a heavy barrage and rescuing an officer.——Eli B. Moss, Major, M. C., U. S. Army, on duty with the 123d Feld Artillery, has been cited for bravery.——Emmett Merrick Harrison, Major, M. C., U. S. Army, Chattanooga, Tenn., has been cited for distinguished service in action near Handiomout and Manhewlls, Nov. 9, 10 and 11, 1918, by the example he set under fire of extreme violence, and by his excellent control of the sanitary detachment of the 323d Infantry, Major Harrison accomplished the evacuation of the wounded in the minimum of time. He also personally established and conducted a first aid station for a neighboring regiment, attending to many wounded of that regiment.——John T. Barbee, Major, M. C., U. S. Army, Jackson, Tenn., has been cited for bravery at Chateau-Thierry.

Weekly Bulletin A. E. F.

(Feb. 17, 1919)

MEDICAL SERVICES OF THE A. E. F.

According to Weekly Bulletin 45, at Base Hospital 116 there were 12,000 patients admitted between June 2 and Dec. 8, 1918. Of these, 4.113 were medical cases. A classification of the deaths shows that of 118 cases of bronchopneumonia, thirty-eight were fatal; of eighty-two cases of lobar pneumonia, sixteen were fatal; of six cases of empyema, four were fatal; of two cases of bacillary dysentery, both were fatal; of three cases of typhoid fever, one was fatal; in six mustard gas cases the patients died of a complicating bronchopneumonia.

At Camp Hospital 52, which was increased in capacity from 250 beds to 1,700 beds, there were admitted 14,293 cases from July, 1918, to Jan. 21, 1919. The medical cases comprised a large number of diseases, affording to the members of the medical personnel a wide range of experience.

WEEKLY REVIEW

Typhoid and paratyphoid show a further fall in incidence. The venereal disease rate has fallen noticeably in the District of Paris and the Arrondissement of Tours. No more cases of smallpox have developed. There has been a reduction in the incidence of chickenpox, diphtheria, meningitis and scarlet fever. The annual venereal disease rate per thousand of strength, for the week ending Feb. 5, 1919, for the whole A. E. F., is *37.26*.

The following cases of certain communicable disease were reported during the week ending February 16:

Section	Chicken-pox	Diph-theria	Dysen-tery	Measles	Menin-gitis	Para-typhoid	Scarlet Fever	Ty-phoid	Total

SICK MEN ON TROOP TRAINS

Sacrifice of life from preventable disease results from permitting sick men to travel on troop or passenger trains. Medical examination of men before entrainment for detection of colds, cough, fevers, rashes, etc., must be thoroughly carried out to prevent the development of pneumonia, meningitis, scarlet fever, etc. Patients with these diseases are taken from the trains every day at numerous coffee stops and traffic junctions in the A. E. F. It is the medical officers' business to save every man who is willing to take a chance in order to get home sooner by ignoring a splitting headache and a sore throat. The men's ignorance of the risks they run must not be allowed to contribute to the A. E. F. death rate.

Typhoid and Paratyphoid in the A. E. F.

Fevers of the typhoid-paratyphoid group have continued to appear in many units of the American Expeditionary Forces during the past five or six months. *Weekly Bulletin 46,* February 24, in detailing some investigations of these diseases in several of the divisions, says that the typhoid-paratyphoid carrier rate among all organizations which passed through epidemics of diarrhea or dysentery has been unusually large during the past six months. There have been fifty-nine cases of typhoid-paratyphoid reported from the 79th division since November 1, and an analysis of the epidemic in this division, which referred particularly to carriers, gave some interesting results. Particular attention was given to the cooks and kitchen help. A total of 336 cooks were examined, which included practically all the cooks of the division. Of these men, fifty-seven, or 17 per cent., gave histories of recent attacks of diarrhea; some of them intermittent. Carriers of typhoid or paratyphoid were found as follows: In the 316th Infantry fifteen carriers were found in three companies, among whom three were found in the kitchen; in the 315th Infantry one case was found in each of two companies, and one carrier was found in each of three kitchens; in the 314th Infantry there were seven cases in two companies and none in the third company. Two carriers were found in the kitchen in the latter company and one each in the other two companies. This shows the possibility of transmission through the agency of the kitchen personnel. More than twenty carriers of typhoid and paratyphoid in the A. E. F. were reported in the six weeks prior to the date of this bulletin.

In this connection, the chief surgeon of the A. E. F., Col. Walter D. McCaw, in Circular 69, dated February 17, calls attention to the continued appearance of this group of diseases, and says that medical officers of the forces have failed to grasp the significance of these reports, and that some officers are careless and do not properly appreciate their responsibilities in this regard. The excuse that "there is a war on" will not be tolerated longer. The circular then gives a summary of the incidence of the typhoid-paratyphoid group of diseases in the American forces, calls attention to the importance of early and complete case reports, takes up the clinical and laboratory diagnosis, their prevention and control, and particularly calls the attention of all officers to Sections 184 and 185 of Article 3 of the Manual of the Medical Department, and enjoins compliance. Accompanying the circular is a copy of the department instructions covering the technic of employing the triple lipovaccines.

HONORABLE DISCHARGES, MEDICAL CORPS, U. S. ARMY

NOTE.—In the following list, L. signifies lieutenant; C., captain; M., major; L. C., lieutenant-colonel; Col., colonel, and B. G., brigadier-general.

Wisconsin

To Camp Custer, Mich., base hospital, from Camp Upton, Lieut. H. C. SALTZSTEIN, Milwaukee.

To Washington, D. C., Surgeon-General's Office, from Camp Dix, Lieut.-Col. N. M. BLACK, Milwaukee.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Asst. Surg.-Gen. C. C. PIERCE, proceed to Chattanooga, Tenn, for inspection of conditions relative to the venereal disease clinics.

Asst. Surg.-Gen. A. J. McLAUGHLIN, proceed to New York and Boston for inspection of public health activities.

Asst. Surg.-Gen. L. L. LUMSDEN (*Reserve*), procced to Lexington, Ky., to address the Kentucky Council of Defense.

Sen. Surg. FAIRFAX IRWIN, report at bureau of conference relative to taking over certain hospitals offered by the War Department.

Sen. Surg. P. C. KALLOCH, deliver lectures on health matters at Rockland, Me., on request of U. S. Shipping Board.

Sen. Surg. J. H. WHITE, proceed to various ports in the West Indies, Mexico and Central America for the purpose of investigating sanitary conditions.

Sen. Surg. L. L. WILLIAMS, proceed to Palo Alto, Calif., to make inspection of an army hospital at that place.

Sen. Surg. J. O. COBB, proceed to Madison, Wis., to address vocational conference at the university.

Surg. J. S. BOGGESS, relieved at San Antonio, Texas, proceed to Alexandria, La., to take charge of cantonment hospital at Camp Beauregard.

Surg. JOHN M. HOLT, directed to confer with commanding officer relative to taking over army base hospital at Camp Logan.

Passed Asst. Surg. G. A. KEMPF, proceed to Perryville, Md., to inspect buildings to determine their suitability for utilization as hospitals.

Passed Asst. Surg. W. C. WITTE, relieved at Des Moines, Ia. Proceed to Washington, D. C., for duty in formation of reserve corps.

Acting Asst. Surg. R. E. GRAMLING, relieved at Leavenworth, Kan. Proceed to Salt Lake City, for duty in venereal disease control.

Acting Asst. Surg. WILLIAM M. KEEN, proceed to Harrisburg, Pa., for duty in influenza control.

Acting Asst. Surg. R. H. TRIMBLE, proceed to Harrisburg, Pa., for duty in influenza control.

Asst. San. Engr. SOL. PINCUS, proceed to Washington, D. C., for temporary duty in connection with studies of stream pollution.

Asst. San. Engr. C. P. RHYNUS, relieved at Nitro, W. Va., proceed to Washington, D. C., for duty in investigations of influenza and studies of stream pollution.

Asst. San. Engr. FRANK R. SHAW, relieved at Lake Charles, La. Proceed to Columbus, Ga., for duty in extracantonment sanitation.

Biochemist M. X. SULLIVAN, proceed to Washington, D. C., for temporary duty at the Hygienic Laboratory.

Asst. Educational Director JOHN A. VAN DIS, proceed to Detroit to attend meeting of the International Convention of Boy Workers, March 17-19.

Regional Consultant LOUIS HOUGH, proceed to Columbus, Ohio, to assist in venereal disease control work.

Asst. Chemist E. J. CASSELMAN, proceed to Springfield, N. J., for studies in connection with the disposal of chemical wastes.

San. Insp. BEN G. MOULTON, proceed to Des Moines, Ia., proceed to Columbus, Ga., for duty in extracantonment sanitation.

Engr. Draftsman B. H. GRAFF, proceed to Perryville, Md., to inspect buildings to determine their suitability for utilization as hospitals.

Pharmacist CHARLES SLOUGH, relieved at the marine hospital at Mobile, Ala. Proceed to Augusta, Ga., for duty in hospital at Camp Hancock.

Pharmacist THOMAS C. ARMSTRONG, proceed to marine hospital at Chelsea, Mass., for examination to determine his fitness for promotion.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Reported Rabies.—H. F. Gray of the California State Board of Health has been making investigation regarding the report of rabies existing in Surprise Valley, Modoc County, and also at Susanville, and has sent to the state laboratory several heads of coyotes supposed to have died from rabies.

Violation of Medical Act.—Dr. T. Leung, Los Angeles, a Chinese herbalist, is said to have been arrested, March 5, charged with the violation of the state medical practice act.——Drs. George F. Frissell and Augusta Stone, Los Angeles, charged with using the mails to promote illegal surgical practices, have their cases set for trial, May 20 and May 21, respectively.

Charged with Fraud.—Indictments charging use of the United States mails in a scheme to defraud are said to have been returned by the federal grand jury, March 1, against R. Haruki, G. Suzuki, T. G. Nacayama, B. Nakaraha, T. H. Hayashi, Watanobi and Ochiai, Japanese physicians who were arrested several months ago on charges of falsifying their examination papers before the state board of health when applying for their certificates to practice medicine in the state.

Personal.—Slocomb R. Edwards, San Francisco, Lieut., M. C., U. S. Army, has been discharged from the service and has been appointed chief of the ear, nose and throat department of Leland Stanford Junior University School of Medicine, San Francisco.——Alanson Weeks, Major, M. C., U. S. Army, San Francisco, has been commissioned lieutenant-colonel and is in command of Base Hospital No. 30, American Expeditionary Forces, France.——J. Ross Moore, Major, M. C., U. S. Army, Los Angeles, has returned from France.

DISTRICT OF COLUMBIA

Personal.—Dr. John P. Frey, Washington, has been appointed assistant health officer of the district.

Public Health Service Hospital Turned Over to District.—Rupert Blue, Surg.-Gen., U. S. P. H. S., announces that the District Influenza Emergency Hospital, conducted by the Public Health Service, at 612 F Street N.W., Washington, has been turned over to the district authorities under recent congressional appropriations made for that purpose. The hospital has been in operation since Jan. 1, 1919, under the charge of Act. Asst. Surg. Ernest W. Scott. During this period 221 patients were attended, of whom 193 have recovered and twenty-eight died.

GEORGIA

Hospital Items.—The New Parkview Hospital at Gainesville was opened to receive patients, March 5. The hospital has accommodation for ten patients, and negotiations are under way to increase the accommodation to twenty-five.

Violation of Drug Act.—In the federal court at Athens, February 21, Dr. Jess W. Power, Athens, is said to have been found guilty on one count of the indictment charging him with violation of the Harrison Narcotic Law in that he failed to make duplication of orders sent to drugstores for drugs. He was acquitted on the charge of the unlawful selling of drugs.

New Officers.—At the annual meeting of the Bartow County Medical Society held in Cartersville, March 5, Dr. Samuel M. Howell was elected president, Dr. William C. Griffin vice president, and Dr. Tanner Lowry secretary-treasurer, all of Cartersville.——Lowndes County Medical Society, at its annual meeting held in Valdosta, February 11, elected Dr. Dewitt W. Freeman president, Dr. Frank H. Thomas vice president, and Dr. Joyce F. Mixson secretary-treasurer, all of Valdosta.——At the annual meeting of Ware County Medical Society held in Waycross, Dr. George N. MacDonell was elected president, Dr. James H. Latimer vice president, and Dr. William F. Reavis, secretary-treasurer, all of Waycross.

Personal.—Ferdinand H. Herrmann, Capt., M. C., U. S. Army, Eastman, after a long service overseas as surgeon, Second Engineers, Second Division, has returned home bringing with him the Croix de Guerre with Palms.——Dr. Harold F. McDuffie, Atlanta, has been appointed a member of the state board of medical examiners to fill the unexpired term of the late Dr. Richard E. Hinman.——Giles Hathcock, Lula, and John L. Walker, Waycross, have been reappointed members of the state board of health for a term of six years.——Frank K. Boland, Major, M. C., U. S. Army, Atlanta, who went overseas with the Emory Hospital Unit, reached New York, February 26.——W. Nevin Adkins, Capt., M. C., U. S. Army, Atlanta, has returned home after six months' service in France.——Dr. Charles D. Cleghorn, Macon, retired as superintendent of the Macon Hospital, March 1.——Dr. Wiley S. Ansley, Decatur, has succeeded Dr. W. J. Houston, who resigned as physician of Dekalb County.——Dr. Henry W. Terrell, LaGrange, has been appointed local surgeon at LaGrange for the Atlanta and West Point Railway, and the Western Railway of Alabama.——The office of Dr. Eli F. Sapp, Albany, was destroyed by fire, February 28.——Dr. George M. Anderson, Ray City, has been elected health commissioner of Moultrie and Colquitt County, succeeding Dr. Lorick T. Patillo, Atlanta, resigned.

ILLINOIS

Personal.—Luther B. Highsmith, Lieut., M. C., U. S. Army, Flat Rock, returned with the officers of Base Hospital No. 22 from abroad and reached Camp Grant, March 12.——Dr. J. Allen Cotton, Peoria, was shot and seriously wounded by a sergeant of the Eighth Illinois Infantry, at Peoria, March 9. ——Dr. William A. Trout, Atwater, was stricken with cerebral hemorrhage while making a professional call between Atwater and Carlinville.——Dr. Francis H. Fleege, Galena, who has been seriously ill with inflammatory rheumatism at St. Francis Hospital, is reported to be improving.

For Better Housing.—A bill has been introduced into the legislature to improve housing conditions in Illinois and ultimately to abolish the slums which exist in almost every large town. The bill is sponsored by Senator Kessinger, and its underlying principles have been endorsed by the governor, who called attention to the need of better housing conditions in the state in his January message to the legislature. The bill contains requirements as to height, size of rooms, lighting, sanitary facilities, etc., of tenement houses, and applies to all cities having a population of 10,000 or over. It vests enforcement in the state and local departments of health.

Illegal Practitioners Prosecuted.—It is reported that, notwithstanding the fact that the appellate court affirmed the opinion of the circuit court of Macon County imposing a heavy fine on James E. Kane of Decatur for violating the Illinois medical practice act by practicing as a chiropractor without a state license, Kane proceeded with his unlawful practices. The Department of Registration and Education collected further evidence against him, on which he was indicted and has again been adjudged guilty by the court. His attorney has entered a motion for a new trial, which will be disposed of in due course. Not satisfied with the opinion of the appellate court that he cannot practice as a chiropractor without a state license, Kane has appealed his case to the supreme court. It was taken on call at this term, and an opinion will probably be handed down at the next term. The appeal is based on the contention that the medical practice act is unconstitutional so far as it relates to chiropractors. ——On complaint of one of the inspectors of the department, it is reported, Eugene Childress of East St. Louis was arrested for practicing medicine without a license. He was found guilty, but did not have enough money to pay the fine. The court sentenced him to six months of hard labor in the Belleville stone quarry.

Chicago

Lethargic Encephalitis.—After a consultation with physicians who have treated cases of this disease in Chicago, the commissioner of health issued a notice that the disease is now a reportable one.

Smallpox.—As the result of the discovery of three cases of smallpox in the Revere House, March 11, more than 100 of the guests and employees of the hotel were vaccinated by health department officials.

Illegal Practitioner Fined.—M. Krawczyk of 904 Milwaukee Avenue is said to have been arrested by the Department of Registration and Education of the State of Illinois for practicing medicine without a license and to have been fined $50 and costs.

Death Rumor Unfounded.—The report of the death of Dr. Samuel J. Walker which has appeared in local papers has not been confirmed. It is believed that the officer who died from typhus fever in Macedonia was a Lieutenant Walker, not a medical man.

Officers Returned from Abroad.—Leon C. Garcia, Lieut.-Col., U. S. Army; Herbert Walker, Major; Eugene Cary, Capt.; Irvin S. Koll, Capt.; Ralph H. Kuhns, Capt., and Lloyd H. Simmons, Lieut., M. C., U. S. Army, who have been on duty with the American Expeditionary Forces in France, have been released from military duty.

Violations of Narcotic Law.—Five Chinamen waived examination before United States Commissioner Louis F. Mason, March 10, and were held on charges of violating the Harrison Narcotic Law. The arrest followed a raid a week before in which $25,000 worth of opium was found and confiscated. ——While the police were searching a laundry in West Madison Street, in which a fire with two fatalities had occurred, about $500 worth of opium and heroin was discovered.

Personal.—Dr. Alice Hamilton has been appointed assistant professor of industrial medicine in Harvard Medical School. She is the first woman to receive a faculty appointment at the Harvard Medical School. Dr. Hamilton graduated in medicine from the University of Michigan in 1893, was professor of pathology in the Northwestern University Woman's Medical School for three years, bacteriologist to the Memorial Hospital for Infectious Diseases, Chicago, for eight years, and has been engaged since 1910 in the investigation of industrial diseases for the federal Department of Labor.——Dr. Abraham L. Lash has been appointed surgeon in charge of the emergency hospital of the Chicago and Eastern Illinois Railway, at Oak Lawn.

INDIANA

Diphtheria in Fort Wayne.—Dr. Maurice R. Lohman, health commissioner of Fort Wayne, reported that there are nine cases of diphtheria in the city among seven families in widely separated districts.

License Revoked.—The state board of medical examiners, February 26, is said to have revoked the license of Dr. George F. Smith, Bicknell, because of alleged misrepresentation when he obtained his license to practice medicine in Indiana.

Smallpox.—Smallpox is reported from Elkhart, La Porte and South Bend.——In Huntingdon County, outside of the city of Huntingdon, there were fourteen cases of smallpox in January, and it is now estimated that there are twenty-five cases, all mild in type.

Asylum Hospital Burns.—The men's building of the Eastern Indiana State Hospital for the Insane, Richmond, was burned, March 5. One patient was burned to death and a second is not accounted for. Twenty-two bedridden patients were removed without injury. The property loss amounted to $25,000.

Personal.—Dr. Frederick A. Tucker, Lieut.-Col., M. C., U. S. Army, Noblesville, who had been in charge of Base Hospital No. 51, near Verdun, since June last, has returned from France.——Dr. Adam L. Schneider, Fort Wayne, has been appointed vice president, and Dr. Lester I. Ofner, treasurer of the Allen County Antituberculosis Society.——John B. Fattic, Lieut.-Col., M. C., U. S. Army, Anderson, has returned from overseas.——Dr. George H. Brodbeck, Roann, is reported to be seriously ill with paralysis.——Dr. John N. Hurty, secretary of the state board of health, has been made a fellow and awarded a life membership in the American Pharmaceutical Association.

KANSAS

Influenza at Wichita.—During the last week in February there were 250 cases of influenza and sixteen deaths in Wichita, the highest figures for any one week during the new year.

Handbook of Child Hygiene.—The division of child hygiene of the Kansas State Board of Health, under the directorship of Lydia Allen DeVilbiss, has issued a handbook of child hygiene, which, among many other topics, discusses the care of the children and the feebleminded, the wards of the state, quoting from reports of investigations into the child caring and maternity homes of the state which show a most unsatisfactory state of affairs. An analysis is given of Kansas child welfare legislation, and a plea is made for a thorough investigation and a complete codification of such legislation.

MARYLAND

Typhoid Fever.—The health department of Baltimore warns all residents of the new annex to the city, including Overlea, Mount Washington, and Roland Park, to adopt all possible precautions against development and spread of typhoid fever.

Personal.—Charles W. Maxson, Capt., M. C., U. S. Army, Steubenville, Ohio, has just been released after imprisonment for nearly eleven months in Germany. Captain Maxson was attached to the Fifth British Army and was captured because he refused to leave the wounded men he was caring for.——Dr. Clarence A. Neymann, Baltimore, has been appointed superintendent of the Cook County Psychopathic Hospital, succeeding Dr. Adam Szwajkart.——Dr. Norburu Ishida Baltimore, is reported to have been indicted by the grand jury of Baltimore County for the murder of Dr. George B. Wolff.——Col. William H. Welch, director of the School of Hygiene, Baltimore, established by the Rockefeller Foundation at the Johns Hopkins University, has sailed for France, where he will attend a health conference of the International Red Cross.——Dr. Alexander J. Gillis, Baltimore, formerly assistant superintendent at Sydenham Hospital, has been decorated with the Military Cross by the British government for bravery and distinguished service in the war. He was gassed while on a visit to the first-line trenches.——Dr. William Y. Hollingsworth, Bel Air, formerly connected with the surgery department at Sparrows Point, has also been decorated with the Military Cross, for bravery and distinguished service.

MASSACHUSETTS

Personal.—Dr. John Parr has been appointed and confirmed as city physician of Methuen to fill the unexpired term of the late Dr. Richard H. Lawler.

Boards of Health Meet.—At the regular quarterly meeting of the Massachusetts Board of Health, held at Pemberton recently, Dr. John S. Hitchcock, Northampton, acted as chairman in the absence of the president, Dr. Francis F. Mahoney, Westboro. A paper was ready by Fred Johnson, secretary of the Civilian Relief Committee of the Red Cross, on "Relief Work in Civilian Communities," and Dr. Charles E. Simpson, Lowell, city health officer, delivered an address on "Large Concentration Camps and Their Relations to Civilian Communities."

MONTANA

Personal.—Dr. Alonzo B. Eckerdt, Helena, has been appointed temporary health officer of Bozeman, succeeding Dr. Joseph Piedalue, resigned.——Herbert H. Judd, M. C., U. S. Army, Bozeman, has been occupied since his return from France in escorting wounded and sick soldiers from New York to hospitals in various parts of the United States.

Reduction in Typhoid.—The biennial report of the Montana State Board of Health shows that in 1917 there were 522 cases of typhoid fever reported in the state, while in 1918 there were only 179. The reduction is ascribed to the field investigation, which resulted in the improvement of the water supply. During this period 122 field investigations or sanitary surveys were made of public water supplies and 193 surveys of private water supplies. There were 833 laboratory investigations and 2,716 analyses of water.

Influenza.—At a meeting of the physicians of Helena, February 21, for the discussion of the influenza situation, it was disclosed that there were at that time 156 cases of the disease in the city, but it was said to be in light form, a characteristic of recent cases. There had been only an occasional death in the previous two months, and none in the previous ten days. It was noted that the disease had lately attacked a greater proportion of children, in whom the disease lasted on an average about five days as against about eight days for adults.

NEW YORK

Personal.—Dr. M. Louise Hurrell, Rochester, director of the American Women's Hospital at Luzanoy, France, and several members of the hospital staff have been decorated by the French government for their work in stamping out typhoid fever in certain cantons of the Seine, the Marne and the Aisne.

Poliomyelitis After-Care.—The records of the state health department show that during the year 1918, forty-two clinics for the after-care of poliomyelitis cases have been held in thirty-five municipalities in this state. The total number of cases examined was 654. Of this number 456 had attended one or more previous clinics. Of these 456 patients who had previously attended clinics and were under the care of field nurses, forty-nine were cured or practically normal, and 296 were improved. During 1918, 823 pieces of new apparatus were delievered to patients. Of the 1,700 patients that have been under state care, about 1,000 are wearing some form of apparatus ordered through the state department of health and applied by the nurses. There were about seventy new cases of poliomyelitis in the state during the year.

Civil Service Examinations.—The Civil Service Commission of the State of New York announces the following examinations to be held, April 26. Applicatons should be made before April 14, to the State Civil Service Commission. Albany:

Director of laboratory, department of health officer; port of New York, Rosebank, S. I., N. Y., salary, $3,500. This position requires a theoretical and practical knowledge of bacteriology as well as the knowledge of general pathology sufficient to conduct examinations to determine diagnosis in quarantinable, communicable, contagious and infectious diseases. Candidates will be rated on their education, experience, and personal qualification.

Laboratory apprentice, state department of health, salary, $720, men or women, preferred age from 18 to 30 years; requirements are a college education or its equivalent, and knowledge of bacteriology and practical laboratory experience is desirable.

Assistant physician, to provide eligibles for the position of assistant physicians in the state hospitals or other institutions of similar nature in various parts of the state. Salary in the state hospital, $1,200, increasing to $1,000, with maintenance, including quarters, board, laundry, etc. Applicants must be licensed medical practitioners of the state, men or women, and must have had six months' experience on the resident medical staff or as medical intern or clinical assistant in a state hospital or institution, or one year in the practice of medicine. Unmarried men preferred.

New York City

Drop in Influenza Cases.—The number of new cases of influenza reported to the board of health, February 14, was the lowest for any day this year, being ninety-five. The pneumonia cases reported continue to average between fifty and sixty daily.

Warns Against "Sleeping Sickness."—Dr. Royal S. Copeland, health commissioner, has issued a statement warning the public against a possible visitation of the disease known as "sleeping sickness." After describing the symptoms of the affection, he admonishes the public on the appearance of those symptoms immediately to summon a physician and to make a report to the board of health.

Hospital Asks Help.—The New York Hospital, for the first time since it was organized, 140 years ago, is making a public appeal for funds to meet a deficit of $100,000 incurred last year. In addition to its main institution in West Sixteenth Street it operates the Hudson Street Hospital and convalescent home and hospital at Bloomingdale. During the war it maintained a fully equipped hospital unit at Chateau Roux for eighteen months.

Hospital for Washington Heights.—At a mass meeting of Washington Heights physicians, held March 10, the Washington Heights Physician's League was organized. Its purpose is to secure a city hospital for this section, where urgent need for added facilities for sick has existed for a long time. The officers of the league are Dr. M. Joseph Mandelbaum, president; Dr. Henry G. MacAdam, vice president; Dr. Lesser B. Groeschel, secretary, and Dr. William F. Bender, treasurer.

Low Infant Death Rate.—Statistics recently issued by the health department show that in 1918 New York had the lowest death rate of babies of any of the ten largest cities of the United States, and the second lowest ever recorded in the history of the city. The lowest rate was recorded in 1917, when there were 88.8 deaths per thousand living births. The 1918 rate was 91.7. The health department considers the showing as extremely gratifying in view of the war with its resultant economic conditions and the influenza epidemic, which deprived many children of proper care and nourishment.

OHIO

Bill to Provide Sanatorium Districts.—A bill, introduced by Senator Davis of Youngstown, and now in the hands of the public health committee of the upper house, is designed especially to relieve unsanitary conditions due to pollution in sparsely populated regions, by the establishment of joint sanitary districts similar to the organization of the conservancy district authorized after the great flood in 1913.

Smallpox.—A year ago there were reported to have been 100 cases of smallpox in Middleton; at present there are only five, and none of them serious.——The board of health of Elyria, at a special session, February 27, to consider the epidemic of smallpox in the city, authorized the health officer, Dr. George E. French, to quarantine the Gates and St. Agnes' schools or any other school or factory, should the welfare of the city require such action.——At Denison, fifteen cases of smallpox were reported to have developed in six hours, and public gatherings have been suspended.

New Health Bill.—Representative Hughes has introduced a bill into the legislature to replace the local health administrative system of the state. Under the provisions of the bill each city of more than 25,000 inhabitants and each county is organized into a health district under a whole-time health officer. This will provide, for all sections of the state, public health directors equal to those now furnished in the largest cities. The bill has the backing of the state federation of labor, the state grange, the Ohio Manufacturer's Association, and other organizations, the governor and health and old age insurance commissions, and the state department of health.

Personal.—Dr. Henry Graefe, Lieut., M. C., U. S. Army, Sandusky, has returned after more than a year of service with the American Expeditionary Forces in France.——Dr. William C. Snodgrass for twenty-three years a practitioner of Kenton, has moved to Los Angeles.——A smoker was given at Columbus, February 29, in honor of Dr. Louis Kahn, retiring health officer of the city.——Dr. W. Clyde Leeper, Akron, has returned after several months' service with the American Red Cross tuberculosis units in Italy.——Matthias A. Wagner, Lieut., M. C., U. S. Army, Lima, who has been for several months on duty with Evacuation Hospital No. 25 in Belgium, has returned home.

The Biggar Prize Essay.—Through the generosity of Dr. Hamilton F. Biggar, Sr., the Cleveland Medical Library Association has instituted a prize essay competition, and this year offers three cash prizes, the total value of which amounts to $600. The competitions are open to men of the medical profession in Cuyahoga County, senior students of Western Reserve University, Cleveland, and interns in hospitals in Cuyahoga County. Prizes will be awarded to the best essay on some clinical subject. Manuscripts should be typewritten and submitted to the secretary of the Cleveland Medical Library Association on or before November 1. These manuscripts should be marked with a fictitious name and accompanied by a sealed envelop bearing this name and enclosing the true name of the essayist.

The Menace of Tuberculosis.—The state department of health announces that there are 50,000 patients suffering from tuberculosis in active stages, each of whom is a potential source of infection to his fellows. The state also lacks facilities for guarding the public against danger from these cases and means for giving treatment for incipient cases. The present hospital equipment for combating the disease consists of the state sanatorium, at Mount Vernon, for incipient cases, three county, two municipal hospitals, six intercounty districts hospitals and several private institutions which care for a limited number of patients. Most of these hospitals are filled to capacity and have extensive waiting lists. The department is encouraging the enlargement of existing hospitals and establishment of new ones, the employment of more public health nurses, and the establishment of county dispensaries.

Cincinnati

Staff Reappointed.—The entire medical staff of the Cincinnati General Hospital has been reappointed by the board of directors of the institution.

Society Changes Name.—The Cincinnati Research Society, March 6, changed its name to the Daniel Drake Society, the new name being in honor of the founder of the Cincinnati Hospital and Ohio Medical College, who died in 1853.

Personal.—Dr. Fred W. Lamb has resigned as assistant profess[illegible] in the University of Cincinnati and as [illegible] the staff of the Cincinnati General Hospital.——Dr. Henry E. Germann has been elected second vice president of the Cincinnati Antituberculosis Home.——Dr. James W. Miller has been appointed attending dermatologist to the Cincinnati General Hospital.

OKLAHOMA

Personal.—Dr. Oliver Bagby, Vinita, who has been seriously ill for a month in a hospital in Kansas City, is reported to be improving.

Physician Wins Verdict.—A jury in the district court of Beckham County awarded damages in the sum of $62,000 to Dr. G. Fowler Border, mayor of Mangum, in his suit for damages against five men who are said to have attempted to entrap Dr. Border into performing an illegal operation. Five of the men implicated in this conspiracy were tried and convicted in October, 1914, and sentenced to pay a fine of $500 and to be imprisoned for six months in jail. A new trial was immediately requested and refused, and notice of appeal was given.

PENNSYLVANIA

Philadelphia

Pennsylvania Unit Ready to Sail.—Members of the Pennsylvania Hospital unit have been sent to a port of embarkation in France and are awaiting transportation to America. There are about 400 members in the unit, including twenty-five doctors, 125 nurses and 250 enlisted men. During its service the unit was attached to the British army.

Pending Milk Bill Bad.—Dr. William Krusen of the department of health renewed the attack on the bill which is before the legislature to permit less butter fat in milk. This measure will allow milk dealers to reduce the quantity of fat from 3.25 to 3 per cent. and the milk solid from 12 per cent. to 11.5 per cent., such reduction to be accomplished by the addition of skim milk. The director urges the public to make a demonstration in the interest of the entire state, and especially of children, against such legislation.

Personal.—Joseph Sailer, Col., M. C., U. S. Army, and Benjamin F. Baer, Charles F. Nassau, and Albert P. Francine, Majors, M. C., U. S. Army, arrived in New York from France, February 26.——Drs. George F. Sowers, Charlotte S. Farrington, Benjamin Brown, Walter M. Miller and Frederick Van Gunten have been appointed additional school medical inspectors.——The following men have been awarded the military cross by the British government for bravery and distinguished service during the war: Thomas L. Doyle, A. Knox, Charles J. Worth and James B. Clinton, Lieutenants, M. C., U. S. Army.——John J. McKenna, Major, M. C., U. S. Army, after a year of service in the hospitals of France, has returned home.

CANADA

Toronto Institute for Blind Soldiers.—Dr. Charles R. Dickson, the roentgenologist, Toronto, himself blind, has been placed in charge of Pearson Hall, an institution recently opened in Toronto by Sir Arthur Pearson while in that city.

The Aesculapian Club, Toronto.—The following have been elected officers for 1919-1920: president, Dr. Herbert J. Hamilton; vice president, Dr. Nelson H. Beemer, Mimico, Ont.; secretary, Dr. Frederick C. Harrison, and treasurer, Dr. Edmund E. King.

Ontario Doctor Honored.—Dr. William Burt, Paris, Ont., a past president of the Ontario Medical Association, was presented with a substantial gift by friends in Paris, March 10, the occasion being his seventieth birthday. The presentation was made by the mayor of the town. Dr. Burt, who was ill at the time of this presentation, died, March 14.

Personal.—Major Benjamin L. Guyatt, Binbrooke, has been appointed officer commanding the Toronto military base hospital.——Capt. Roy H. Thomas, M. C., has returned to Toronto from overseas, and has been assigned to duty in Toronto military district.——Dr. William J. McCollum, Toronto, has returned from Florida much improved in health.——Lieut.-Col. Henry R. Casgrain, Windsor, Ont., has returned from overseas.

London University Seeks Aid for Medical Faculty.—The Ontario government received a deputation last week from the University of London, Ont. In the deputation were Dr. Edward A. Braithwaite, Edmonton, Alta., president of the university, and Dr. Hugh A. McCallum, London, Ont., dean of the medical department. They asked for $150,000 for extending the accommodation of the medical department. The citizens of London have already subscribed $100,000, and the site, costing about $22,000, has already been secured. The prime minister gave the deputation great encouragement, and stated that his government was already considering substantial aid both to London and Queen's University at Kingston.

GENERAL

Red Cross Nurse Fund.—The American Red Cross, March 9, announced an appropriation of $100,000 as a scholarship fund to induce graduate nurses released from the Army and Navy Nurse Corps to train for public health service.

Society for the Study of Epilepsy to Meet.—The next annual meeting of the National Association for the Study of Epilepsy will be held at the Craig Colony for Epileptics, Sonyea, N. Y., June 6-7, under the presidency of Dr. William T. Shanahan, Sonyea.

Bequests and Donations.—The following bequests and donations have recently been announced:

Grady Hospital, Atlanta, Ga., $500,000; Crippled Children's Home, Atlanta, $100,000; Atlanta Home for Incurables, $5,000, by the will of Albert D. Steiner, Atlanta.

Morton F. Plant Hospital, Clearwater, Fla., $1,000, the proceeds of a Washington's Birthday celebration at the Hotel Lake Belleview, Bellaire, Fla.

Episcopal Hospital, Philadelphia, a trust fund of $5,000 contingent on the death of the beneficiary, by the will of Ellen Craig.

After-War Activities of Red Cross.—The International Red Cross Committee at Geneva has called a convention of the Red Cross organizations of the world to meet at Geneva thirty days after the declaration of peace. This call was issued at the request of the Red Cross societies of the United States, France, Great Britain, Italy and Japan, whose representatives have constituted themselves a committee to formulate and propose an extended after-war program of activities in the interests of humanity.

Lethargic Encephalitis.—Reports of this disease are being made from an increasing number of places throughout the country. What was reported to be the first death from the disease occurred in New York, March 13. The patient was an adult 35 years of age. Forty cases were reported in the city of New York up to March 15. In Illinois, March 11, eighteen deaths had been reported to the state health department out of a total of twenty-seven cases, most of which were in Chicago. The disease had been reported, however, from Evanston, Springfield, Tallula, Alton and Marseilles. The first case reported in San Francisco, March 14, was that of a streetcar motorman. The disease has been made notifiable in a number of places.

Care of Insane Soldiers.—Under the regulations just announced from the Surgeon-General's Office, soldiers who are suffering from insanity will not be transferred to St. Elizabeth's Hospital, Washington, until it is demonstrated that they are incurable or require a long period of treatment. Insane subjects may be recommended for transfer to St. Elizabeth's Hospital after four months' observation and treatment in certain military hospitals designated for the reception of these cases. Exceptions are to be made in well defined cases of paresis, insane epileptics, or violent cases of insanity in which the prognosis is poor and the patient cannot be safely cared for in military hospitals. General Hospital No. 13, Dansville, N. Y., will receive only mild cases suitable for treatment in open wards. Many states have signified their willingness to receive, care for and maintain at state expense soldiers from their states who require institutional care, when the insanity existed prior to enlistment. No patients will be sent to any state institutions until assurance has been obtained from state authorities that the care of the patients is provided for.

Influenza and Pneumonia.—Reports throughout the United States indicate that influenza has markedly abated. Among the states especially reporting a decrease are Wisconsin, Indiana, Kentucky, Kansas and Illinois. At a few points, however, there have been slight decreases. The decrease is accompanied, of course, by a decrease in the number of pneumonia cases. Warnings are given by the local health authorities everywhere, however, not to relax precautions, and to remember that pneumonia sometimes follows an attack of influenza after a considerable interval. In Bozeman, Mont., March 7, there was a considerable rise in the number of influenza cases. On account of the city having no whole time health officer, a physician was brought in from Helena to take charge of the situation. The situation in the Army camps in the United States was reported, March 14, as satisfactory, there being a decided decline in the number of influenza and pneumonia cases, as noted in the report of the Surgeon-General. A considerable number of cases was reported among the troops in France. Illinois deaths from influenza and pneumonia during the epidemic amounted to about 100,000. As reported from North Carolina, the figures of the state board of health indicate that the precautions used against the spread of influenza had a tendency to decrease greatly the number of cases of whooping cough, measles, diphtheria and other contact diseases.

FOREIGN

Influenza.—Reports from Mexico during February were to the effect that 436,200 deaths had occurred from epidemic influenza during 1918. This was believed to be a conservative figure. The disease was still prevailing.

Typhus.—Press reports from Paris, March 10, were to the effect that there is a serious epidemic of typhus in Moscow, with many deaths. Disinfectants, medicines and soap are scarce. The shortage of fuel and scarcity of hot water make it difficult for the population to protect itself against the disease.

School of Herbalists at Parma.—The professor of materia medica at the University of Parma, Italy, has petitioned the government to found a school to train in practical knowledge of medicinal plants. One of the greatest difficulties in the cultivation of medicinal plants is the lack of knowledge concerning them and the inability to get practical expert advice on the recognition, growth and means of harvesting drug plants, those that grow naturally as well as those artificially cultivated. This it is hoped to remedy by the new training school which is to be in charge of Prof. A. Valenti, and connected with the school of pharmacy.

Paris Made Center for Red Cross Work in Europe.—In conformity with plans to carry out Red Cross postwar activities, the commission for Europe, established last November to consider and advise the war council in respect to all policies for the American Red Cross in European countries and to perform various other functions, has been abolished and the office of a commissioner for Europe has been created, and Mr. Robert E. Olds, one of the pioneers of the commission for France has been appointed commissioner with the assimilated rank of lieutenant-colonel, permanent headquarters to be maintained in Paris.

Allied Medical Aviation Congress.—The *Policlinico* relates that a representative gathering was held at Rome last month to discuss the medical and sanitary aspects of aviation. France was represented by Ambard, Guillain, Lemaire, and Garsaux; England by Henry Head, Dreyer, Flack and Birley; Belgium by Wonckin and Brohee; America by Boggs, Wilner and Rowntree, and Italy by Della Valle, Bressanin, Galeotti and Gradenigo, inspector of the psychophysiologic centers for aviation and the engineer Galanti. Others took part also, among them General Morris, director general of aeronautics. Resolutions dealing with physiologic and psychologic tests of candidates for licenses as pilots, the control of flights to high altitudes, and the use of oxygen by aviators were presented and will be sent to the peace conference with the request that they be taken into consideration when the international aerial code is drafted.

American Students at French Universities.—The *Paris Médical* of Feb. 8, 1919, states that arrangements have been made to distribute 5,000 American soldier students among the various departments of the University of Paris. The *Journal de Médecine de Bordeaux* also announces that 1,600 American soldier students are expected to arrive soon to enter the various courses of the University there, and in particular the courses of the Faculté de médecine. The mayor of Bordeaux has issued an appeal to the people of the city and suburbs to let him know of families which will take these young men into their homes and on what terms. The *Journal* adds "In informing our readers of this good news, we address to the American students, who have so valiantly accomplished their duty against the common foe, our best greeting and welcome. We are certain that they will find among our population and among their French university comrades the warmest reception."

Scientific Medicine and Pan-Americanism.—Dr. Paz Soldan of Lima, Peru, founder of the well known monthly, the *Reforma Medica,* in a recent number editorially comments on the importance of "solidarity between the professionals of the New World" as he expresses it. He continues, "In the North, the country of Wilson, after having spread over the red flood of Europe the rainbow of its unselfish abnegations, is turning its eyes toward the South and is commencing to take a serious interest in establishing closed and more sincere relations with its other sisters of America. The appearance of a great Spanish journal, designed originally in English, as will be the one to be published by the American Medical Association is a symptom revealing the profound spiritual change that characterizes the present hour. In Hispano-America the connection and personal relations between the physicians, the thinkers and the statesmen are growing every day deeper and more sincere. . . . To bind men and to bind countries together, that is the program for our future activity, that is the star which will guide our uncertain steps. We know well that in this task we will not be alone, but that hundreds of other medical journalists will march along with us, won over, like us, to the new American ideal, and all working together to realize it in a short time. The new year on which we have just entered, year of peace and life, ought to be as well the year of America, of Pan-America, united and strong by its spirit, by its intellectual originality, by its community of purpose, and by the inexorable mandate of its common destiny."

The Recent Decline of Plague in India.—India has been suffering intermittently for more than twenty years from plague, which has caused the death of some 10,000,000 people. There are now signs that the periodic epidemics are becoming less virulent, and for a curious reason: Experimental investigation has shown that the newer generations of rats are developing comparative immunity from plague infection. It is thought that in time the rats in long-infected areas may become completely plague proof. This eventual outcome has been predicted by Dr. C. J. Martin, F.R.S., director of the Lister Institute, who organized the researches which demonstrated that the infection is conveyed to man by rat fleas. Perhaps in some similar manner plague disappeared in the British Isles. British rats may gradually have become immune to plague infection. However, it must be remembered that plague remained persistently endemic through the centuries in certain quarters of the world, such as the highlands of Yunnan in China and of Asir in Western Arabia, and India has always been regarded as a reservoir.

Conflict Between Profession and Government in Tasmania.—The Tasmanian Branch of the British Medical Association has on several occasions protested against the abuse of the hospitals, and in February, 1917, passed a resolution that well-to-do patients should not be admitted into state-aided hospitals. The association decided that unless the assurance was given by the premier, that such abuse shall cease, to instruct all its members to resign forthwith from the honorary staffs of such hospitals. As the assurance was not given, the honorary medical officers at the hospitals resigned. A conference was held between the premier and delegates of the branch, but proved futile. To fill the vacancies in the Hobart hospital, five physicians were appointed at salaries in defiance of resolutions of the Tasmanian Branch of the British Medical Association, as well as of the Australasian medical congress. Much bitter feeling was aroused by politicians and the press, the attempt being made to show that the medical profession had jeopardized the welfare of the sick poor. In October, 1917, the chief secretary introduced a new hospitals bill in accordance with the policy of the government that there should be no differentiation between persons seeking medical relief in a state-aided hospital. The bill passed through three stages in the lower house and was then sent to the legislative council. All endeavors to come to terms with the profession failed, and in June, 1918, the premier announced his intention to amend the medical act with the object of enlarging the field from which the medical profession in Tasmania might be recruited. Attempts were made to come to terms, but retention of the five physicians who had defied the resolutions of the profession proved insuperable obstacles. A conference was proposed between the government and the Tasmanian Branch of the British Medical Association, but the latter insisted on the removal of the five physicians as a preliminary step. This was refused and so the impasse continues.

MEXICO LETTER

MEXICO CITY, March 9, 1919.

Ratification of Credits

The Universidad Nacional has decreed that persons who have taken courses in other state institutions or in other lands must have their credits ratified before they can follow the courses at the university. When students are sent out of the country on a traveling scholarship by their own university, the credits obtained will be accepted as valid, as also those of persons who have degrees from foreign professional schools if they have rendered services to the government during the last six years. They are entitled to practice their profession if they will merely have their respective diplomas revalidated, ratified, provided that this is done before December, 1920, and that they can present satisfactory documents to prove the services rendered.

Spanish Scholarships for American Students

According to cable despatches, the professor of sociology at the University of Madrid has petitioned the Spanish government to open the universities of Spain to the youth of Latin America, allowing them access to the various faculties, the archives and especially those of the Indies which are preserved at Seville. According to the plan proposed, several scholarships would be founded, providing a minimal allowance of 3,000 pesetas annually, which would be conferred on suitable pupils in the schools established in Latin America.

English in the Daily Papers

There is no paper published here in English, but two of the dailies to remedy this defect have now introduced a section entitled "Anglo-American Notes." The section in the *Universal* is edited by A. Grandville Patton.

Personal

Dr. T. G. Perrín has been elected to membership in the scientific society, the "Antonio Alzate."——Dr. R. Silva has returned from a trip to the United States.——Dr. N. R. Amerena, of the medical school at San Luis Potosi, has recently been appointed professor of medical pathology at the Escuela Nacional de Medicina in this city.

LONDON LETTER

LONDON, Feb. 26, 1919.

The Influenza Epidemic

The third wave of the influenza epidemic continues. In the interval since the second wave the smallest number of deaths from influenza in London in any week was thirty-three in the week ending January 25. In the two following weeks the number rose from fifty-eight to 100 and then to 273, a number which has not been exceeded since December 14. The disease is prevalent all over the country. In Durham all the elementary schools have been closed for three weeks, and whole families are stricken. In Leeds all the elementary schools and the Sunday schools have been closed. In Edinburgh 316 deaths occurred, being the rate of 48.6 per thousand, the highest figure ever recorded, although the week before last an identical number was recorded. This high mortality was largely due to influenza. As preventive measures, gargling the throat and washing the nostrils with a solution of common salt and potassium permanganate is recommended by the health authorities. Masks have been discussed in the press, but so far have not been adopted. Sir Arthur Newsholme, chief medical officer of the Local Government Board, advises them for nurses in cases of pneumonia complicating influenza. In New South Wales their use has been made compulsory, and church services in Melbourne are allowed only on condition that every worshiper wear a mask.

Seven Diseases Made Notifiable

The return home from the various seats of war of large numbers of soldiers suffering from infectious diseases is a source of danger to the civilian population that has exercised the health authorities. An order has therefore been published making malaria, dysentery, trench fever, acute primary pneumonia, enteric fever, relapsing fever and typhus fever notifiable as epidemic and infectious diseases. It is explained that the expression "dysentery" includes amebic and bacillary dysentery, and the expression "enteric fever" includes typhoid and paratyphoid fevers. Every physician, as soon as he becomes aware that a person on whom he is in attendance is suffering from any of the complaints in question, must send to the health officer for the district a notification of the case, unless he knows that it has been reported from another source within the preceding six months. The health officer will immediately take steps to investigate the source of infection and to prevent it spreading. In the case of trench fever or of malaria, in which he has reason to believe that infection was contracted in the United Kingdom, he must forward the name and address of the patient to the Local Government Board, and the same procedure must be adopted if there is an outbreak of dysentery in his district. In every case of malaria, trench fever or dysentery, the health officer will take the necessary steps to secure treatment of the case in a suitable hospital unless he is satisfied that treatment elsewhere will be carried out with all precautions necessary to prevent the spread of the disease. In every case of malaria the health officer will see that if necessary the patient is supplied with efficient mosquito netting, and receives necessary quinin treatment and proper advice as to the continuation of the treatment in order to prevent relapses. If two or more cases occur in a district, a physician may be appointed to make systematic visits to the houses to examine persons who may be infected. In any case, when dysentery occurs the health officer may require that the person shall discontinue any occupation connected with the preparation or handling of food or drink for human consumption. Children in charge of any person specified must not be sent to school. In cases of trench fever the health officer may require that steps immediately be taken to obtain the complete destruction of the lice on the person and clothing of every occupant of the building, and the temporary segregation of other inmates of the building, or persons recently in contact with the patient, until their persons and clothing have been completely freed from lice.

Birth Rate and Empire

The National Birth Rate Commission is investigating the problem of the declining birth rate as it affects the empire, the contemporary movements of population in the dominions, and the proportional distribution of the sexes throughout the empire. It has recommended a complete census shortly after the war and the establishment of a permanent anthropometric department in the ministry of health, a complete constitution for which ministry the national council will issue almost immediately which will show how it may be made an instrument of reconstruction. J. M. Robertson, M. P., submitted to the commission a supplementary statement on the Australian birth rate. The Australian rate, which in 1890 stood at 35, having fluctuated only slightly from 35.3 in 1881, began steadily to decline till, in 1896, it had gone below the British rate. The latter, however, went on steadily declining till 1914, whereas the Australian rate slightly recovered in 1904 and remained steady till 1910, when it began rising, till in 1912 it stood at 28.7; a slight fall then again appeared, till in 1914 it stood at 28.1, while the English was 24. The whole Australian figures, while marked by a slow recovery from the lowest in 1903 (25.3); show no further tendency to rise since 1912, and still mark Australia as a country with an obviously restricted birth rate. The commission is to devote a number of sittings to the problems of the food supply of this country and the optimum population that it can healthily maintain.

The Clinical Meeting of the British Medical Association

The special meeting of the British Medical Association in London was announced in a previous letter. The meeting will be held from April 8 to 11 at the Imperial College of Science, South Kensington. Compared with the ordinary meetings, it will be much curtailed. There will be only three sections, and most of the subjects will be connected with the war. Papers and discussions will occupy from 10 a. m. to 1 p. m., and demonstrations will be given at the hospitals in the afternoons. In the Section of Medicine, Lieut.-Col. F. W. Mott will open a discussion on war neuroses, April 9. April 10 (in conjunction with the Sections of Preventive Medicine and Pathology) influenza will be discussed. The recent epidemics in England and France will be compared. April 11, under the chairmanship of Sir William Osler, venereal disease will be introduced by Brevet-Col. L. W. Harrison. Prognosis in cardiovascular affections will be introduced by Dr. Thomas Lewis under the chairmanship of Sir James Mackenzie. Demonstrations will be given as follows: neurologic cases, National Hospital for Paralyzed and Epileptic, Queen Square; disease of the chest, Brompton Hospital; mine gas poisoning, Lieut.-Col. D. Dale Logan; newer methods in cardiodiagnosis, National Heart Hospital; air force tests, cases and specimens (cardiac), Dr. Thomas Lewis, University College Hospital; venereal diseases, Lieut.-Col. L. W. Harrison, Military Hospital, Rochester Row; war neuroses, Lieut.-Col. F. W. Mott, Maudsley Clearing Hospital, and diseases of children, Hospital for Sick Children, Great Ormond Street.

In the Section of Surgery the subjects will be: gunshot wounds of the chest, introduced by Col. T. R. Elliot and Col. G. E. Gask; wound shock, introduced by Prof. W. M. Bayliss and Dr. H. H. Dale, and reconstructive surgery, introduced by Major R. C. Elmslie. Demonstrations will be given as follows: orthopedic methods, at the Military (Orthopedic) Hospital, Shepherd's Bush; specimens illustrating wounds of arteries, at the Royal College of Surgeons; roentgen ray and facial injuries, at Sidcup; injuries of the eye, and specimens illustrating fractures of the skull, at the Royal College of Surgeons, and specimens illustrating gunshot wounds of the abdomen, at the Royal College of Surgeons.

In the Section of Preventive Medicine and Pathology, the dysenteries will be introduced by Lieut.-Col. L. Dudgeon. Malaria will also be discussed.

The remarkable war collection at the Royal College of Surgeons, which was described in a previous letter, will be on view daily, and three demonstrations have been provided: Sir George Makins, injuries of arteries; Prof. Arthur Keith, fractures of the skull, and C. S. Wallace, abdominal injuries.

Reform of the Indian Medical Service

In response to a deputation from the British Medical Association, Right Hon. E. S. Montagu, secretary of state for India, has announced certain reforms: The pay is to be increased by 33⅓ per cent. Opportunities will be given to medical officers to engage in research, and leave will be granted for the purpose of study. Facilities will be given for private practice, but this must be under the control of the government.

Physiology and the Food Problem

In a lecture at King's College, Prof. W. D. Halliburton, F.R.S., described some interesting researches made during the war by the food war committee of the Royal Society. About the middle of 1917, the fat shortage became serious, so much fat was used in the manufacture of explosives. The question arose as to whether the fatty acids remaining after the extraction of glycerin from fat could be used for the purposes for which fats had been previously used. The first experiments were made on rats. These animals are comparatively short-lived, and if fed on a particular diet for a few weeks or months it is equivalent to feeding a long-lived animal, such as a man, over a longer period. On a diet of fatty acids the rats thrived and multiplied, and it remained to try the effect of the food on man. Prof. Noël Paton obtained voluntary assistants for the test, and the experiment proved a complete success. There is as yet no need for a diet of this kind, but in case of emergency a source of a supply for fat is here indicated. A curious fact came out in these experiments: it was found that if an animal was fed on fatty acids, they passed into the blood stream as fat, the animal making its own glycerin, possibly sugar. Another investigation was made on lanolin. The government had some thousands of tons in stock, and information was asked for as to whether this could be used for food. It has an entirely different chemical constitution from fat. It is not poisonous, but it proved to be quite useless for food on account of its nondigestibility.

National Health

Sir Arthur Newsholme, medical officer of the Local Government Board, who is about to retire, gives in his last report a general survey of the improvement in the national health in recent years. A comparison of the death rate at different ages in the period 1911-1915 with that of 1871-1880 shows that at all ages up to 45 there has been a reduction in the death rate from all causes of from 42 to 50 per cent. in England and Wales. An increase in the average expectation of human life of ten years for males and eleven for females is also a notable fact of the progress that has been made during this period. Of the annual saving of 234,955 lives, represented in the returns showing improvement in health, 64 per cent. is ascribable to reduced mortality from acute and chronic infectious diseases, including the ordinary infectious diseases, as tuberculosis and respiratory affections. Perhaps the best index of combined social and sanitary progress is the reduced death rate in young children, which shows a substantial national gain in child life. The almost complete disappearance of typhus fever, and the gradual vanishing of typhoid, can fairly be regarded as due to public health administration during the past forty years. In Sir Arthur Newsholme's opinion the needs of the future might be considered as coming chiefly under the heads of: (1) more extensive research into the causation of disease; (2) extensions of communal action for prevention and treatment; (3) more complete medical training for the work, and (4) the simplification and strengthening of administrative machinery.

PARIS LETTER

Paris, Feb. 20, 1919.

Electric Treatment of Muscular Atrophy

War wounds and conditions entailed by them are the cause of so many instances of muscular insufficiency that it may be said that hardly a single wounded soldier has escaped without having some of his muscles or muscle groups affected unfavorably. At the last meeting of the Académie des sciences, Dr. J. Bergonié, professor of biologic physics and medical electricity in the Bordeaux medical faculty, stated that industrial or, still better, agricultural work, done day in and day out, would be efficacious, but that this is not always possible, for personal reasons, or because of wounds sustained, season, etc. He advocates for the purpose a method of intense rhythmic faradization which would help to overcome these difficulties. He aims to produce a very pure induction wave by means of a *trembleur* or a special machine, with frequency just sufficient to tetanize the muscle, and by makng use of very large electrodes, an energetic rhythmic functioning of the muscle is thus realized, without provoking any sensation of nervous or muscular fatigue. This passive electrical muscle exercise brings about, without voluntary participation of the will of the patient, an intense assimilation of nutrition and more rapid muscular development than would be produced by voluntary exercise, so much so that the power of motion is quickly restored and the general condition of the patient is improved rapidly, favoring an early recovery.

Provisioning Paris

In order to combat the high cost of living in Paris, which is increasing day by day, M. Vilgrain, undersecretary of state for the food commission, has conceived a project for supplying foods and prime necessities of life for the city of Paris. Barracks will be constructed in all the arrondissements of Paris, at least four in the less populated districts and six or eight in the others. In these barracks one may purchase rice, dry vegetables, concentrated milk, ham, salt meats, frozen meats, pies and edible fats, etc., at a price very much lower than that asked by the retail merchants. These barracks, which will be practically municipal markets, will be supplied abundantly with food by the food commission from the large stocks purchased to provision the army and which are becoming every day more easily obtainable for civilian use because of the demobilization of the army. These municipal stores will not have an exclusive monopoly on the sale of foods furnished by the food commissioner. Merchants, generally, can obtain them if they will agree to sell them at a price fixed by the commission. It is probable that 120 of these barracks will be opened soon. As the merchandise will be sold by eighty municipal butcher shops and 300 controlled groceries, the population of Paris will be able to buy food in about 500 stores at a rigorously controlled price, one which will be lowered every fifteen days. On the other hand, M. Victor Boret, minister of agriculture and food commissioner, has promised to deliver to the city of Paris, from now on, 200 additional tons of refrigerated meats per day. This meat will be placed on sale by the controlled meat markets. This additional supply represents two fifths of the total meat consumption of the people of Paris.

Importance of Proper Selection and Distribution of Cases for War Surgery

Dr. Quénu, professor of clinical surgery in the Paris Medical Faculty, recently directed the attention of the Société de chirurgie de Paris to the fact that in war surgery good final results depend in large part on the proper sorting and distribution of cases. He regards the methods employed in the III-e Armée as being ideal in that respect. The detached division ambulances, formerly charged with the selection of the cases as the wounded arrived from the first aid posts, finally turned over this part of their work to a special service which has a sufficient personnel and surgical material. This body exercises a triple function: (1) a selective rôle; (2) operating and hospitalizing; (3) evacuation. The moderately and the severely wounded who can be transported are sent to the appropriate center in the rear or on the side lines after the necessary provisional fracture apparatus has been applied. The nontransportable wounded are operated on, such as cases of abdominal wounds, hemorrhagic cases, certain cases of thorax wounds, and cases of extensive wounds of the extremities, if the condition of the patient permits of intervention. Patients with tourniquets are held. The slightly wounded are sorted out and are sent to special points of embarkation. The matter is still further complicated by the large number of the gassed and of those having sustained a joint resection or an amputation. These patients must be sifted out and sent to special centers.

The services of this *triage* group are not necessarily rendered at only one point. The primary selection of the slightly wounded from the others is always of great importance, and it is important to do this work as soon as possible, because these slightly wounded and slightly crippled encumber the means of transportation, to the detriment of the more severely wounded. It was even arranged to have special points of embarkation for the resection cases. This leaves at the *centre de triage* only the nontransportable, who are retained, while all the others are evacuated. Here again, a distinction has to be made between the severely wounded who are transportable only to the neighboring surgical centers, and the less severely wounded, who, because of the nature or site of the wound, are not only transportable but can be sent to hospitals farther along the lines of communication, provided always, that as they have not been operated on at the front, the operation can be done inside of twenty, twenty-four or twenty-six hours after the wound. There are, thus, three zones of operations: (1) the first or primary zone at the *centre de triage,* the sorting center of the corps d'armée; (2) the secondary zone comprising the surgical centers in the vicinity of the former; (3) the territorial zone (zone des étapes or zone de l'intérieur) the distance of which should be measured by hours of transport rather than by kilometers.

By whom should the *triage* be made? Without doubt by the consulting surgeon of the corps d'armée, who need not be a good operator. He must, however, be a good organizer, energetic, prompt in decision and capable of meeting any emergency which may arise so far as his corps d'armée is concerned, being able to adapt his work to an advance or withdrawal. As for the technical *liaison* or cooperation between the various corps d'armée, this will naturally fall also on the shoulders of the surgical consultant who should possess all the qualities of mind mentioned above.

Sequels of Gassing in Warfare

At the last meeting of the Académie de médecine, Dr. Ch. Achard, professor of pathology and general threapeutics in the Paris medical faculty, spoke of the sequels of gas poisoning. He based his conclusions on the examination of 3,525 cases seen in the course of two years, 84 per cent. of which were caused by gas of the mustard gas type, and 16 per cent. by suffocating gas. It is remarkable that in the latter cases the most serious sequels are seen. The most important of these late symptoms (they may appear as late as forty months after the gassing) are manifested by the lungs. They are emphysema and chronic bronchitis mainly, but a condition simulating tuberculosis (slight hemoptysis, auscultatory signs at the apexes, fever, loss of weight) or without tubercle bacilli in the sputum. Nevertheless, tuberculosis may supervene as a secondary complication, but much less frequently than is believed to be the case, and only as a lighting up of an old focus. In addition to these pulmonary lesions, there may be lesions of the larynx, eyes, skin, stomach, heart and, exceptionally, of the liver and kidneys. Nervous disorders may develop or disturbances of the general health of the gassed person.

Marriages

John Z. Mraz, Capt., M. C., U. S. Army, Oklahoma City, at present commanding a field hospital in France, to Miss Elizabeth Isabel May, Army Nurse Corps, at Fort Worth, Texas, in June, 1918.

Morris Abel Slocum, Lieut., M. C., U. S. Army, Pittsburgh, to Mlle. Clemantine Marie Louise Mistiaen of Antwerp, Belgium, in London, England, March 1.

Frederick George Speidel, P. A. Surg., Lieut., U. S. Navy, Louisville, Ky., to Miss Teresa Anne Henry of Washington, D. C., February 26.

Deaths

Richard Brooke Maury, Memphis, Tenn.; University of Virginia, Charlottesville, 1857; Bellevue Hospital Medical College, 1858; aged 85; a member of the Tennessee State Medical Association; for four years a surgeon in the Confederate Service during the Civil War; professor of theory and practice of medicine in Memphis Medical College from 1869 to 1872, and of gynecology in the Memphis Hospital Medical College from 1895 to 1897; president of the American Gynecological Society in 1906; and once president of the board of education of Memphis; president of the City Club of Memphis from 1907 to 1911; died at his home, March 17.

Robert Boyden Underwood ⊕ **Capt., M. C., U. S. Army,** Memphis, Tenn.; University of Nebraska, Omaha, 1904; aged 38; instructor in the University of Tennessee; district surgeon of the Illinois Central, and Yazoo and Mississippi Valley railroads; formerly captain in the medical department of the National Guard of Tennessee; commanding officer of the 118th Field Hospital, 105th Sanitary Train, 13th Division, and also in charge of the advanced dressing station; died in the American Red Cross Hospital, Rouen, France, November 12, from pneumonia.

Edgar L. Griffin, Atlanta, Ga.; Southern Medical College, Atlanta, Ga., 1894; aged 47; a member of the Medical Association of Georgia; formerly professor of abdominal and gynecological surgery in the Southern College of Medicine and Surgery, Atlanta; a veteran of the Spanish-American War, in which he served as medical officer; for many years a member of the visiting staff of the Grady Hospital; who was injured in a collision between automobiles, March 2; died a few hours later at the Grady Hospital.

Haroutyoun Tiryakian, New York City; University of Paris, 1874; aged 74; at one time president of the Armenian Political Chamber at Constantinople, and a leader in the Armenian nationalization movement; who made his escape to Persia in 1896, and for nine years was physician to the Shah; a resident of New York for twelve years; died in the Manhattan Square Sanitarium, March 2, after an operation.

Charles Gilchrist Briggs, Schenectady, N. Y.; Albany (N. Y.) Medical College, 1889; aged 53; a member of the Medical Society of the State of New York; who joined the American Volunteer Ambulance Corps in June, 1916, serving first with the British and then with the French army, and who was awarded the Croix de Guerre for removing French wounded under fire at Verdun; died at his home, March 2.

Walter Henry Fox ⊕ **Capt., M. C., U. S. Army,** Waucoma, Iowa; State University of Iowa, Iowa City, 1905; aged 36; assistant professor of anatomy in his alma mater; who was on duty with Base Hospital No. 85 in Paris until January 18, when he was transferred to the Balkan Commission and sent to Belgrade, Serbia; died in Serbia, February 22, from septic pneumonia.

Willis Benjamin Harrison ⊕ **Lieut., M. C., U. S. Army,** Buffalo; University of Buffalo, N. Y., 1916; aged 27; who entered the Army on Oct. 23, 1918, and was ordered to Camp Greenleaf, Ga.; was honorably discharged, December 29, and was recommissioned in the Medical Reserve Corps on the same date; died at Silver Creek, N. Y., February 4, from pneumonia.

Harry Hibberd Weist ⊕ New York City; Bellevue Hospital Medical College, 1891; aged 50; formerly a member of the staff of the Reed Memorial Hospital and St. Stephen's Hospital, Richmond, and surgeon of the Grand Rapids and Indiana Railroad; died at his home, March 6, as the result of a bullet wound, believed to have been self-inflicted.

Robert B. Jessup, Vincennes, Ind.; Bellevue Hospital Medical College, 1883; aged 62; who had been under treatment for several months in Cincinnati on account of disease of the eye; died in his room in the Hotel Emery, Cincinnati, March 4, from the effects of a gunshot wound of the head, self-inflicted, it is believed, with suicidal intent.

Solomon C. Page, Visalia, Calif.; College of Physicians and Surgeons, St. Joseph, Mo., 1880; University of Louisville, Ky., 1887; aged 73; for many years a practitioner of Atchison County, Kan.; but since 1895 a resident of California; died at his home, February 26, from pleuropneumonia.

Herman Bennett, New Lexington, Ohio; Eclectic Medical Institute, Cincinnati, 1896; aged 46; a member of the Ohio State Medical Association; while driving in his automobile over a grade crossing of the Toledo and Ohio Central Railroad in New Lexington, March 3, was struck by a train and instantly killed.

Andrew S. Dickey ⊕ Tipton, Ind.; Central College of Physicians and Surgeons, Indianapolis, 1881; aged 68; local surgeon to the Lake Erie and Western Railroad and to the Northern Indiana Traction Company; health officer of Tipton County; died at his home, March 2, from angina pectoris.

Charles Thomas Mason, Clear Spring, Md.; Jefferson Medical College, 1896; aged 53; died at his home, March 5, from the effects of a gunshot wound of the head, self-inflicted, it is believed, with suicidal intent, while irresponsible on account of a nervous breakdown.

Max Staller ⊕ Philadelphia; University of Illinois, Chicago, 1895; aged 51; one of the founders and first president of Mount Sinai Hospital, Philadelphia; medical director of the Jewish Consumptive Institute; died at his home, March 2, from carcinoma of the throat.

John G. Hersh ⊕ East Greenville, Pa.; University of Pennsylvania, Philadelphia, 1876; aged 66; a member of the state house of representatives in 1899; a specialist in diseases of the eye, ear, nose and throat; died at his home, February 23, from bronchial pneumonia.

Francis Rand Blanchard ⊕ Eaton Rapids, Mich.; University of Michigan, Ann Arbor, 1891; aged 55; chairman of the local chapter of the American Red Cross; was killed, March 4, by a fall down the elevator shaft of the Harriett Chapman Hospital, Eaton Rapids.

Henry Arthur Greiner, Fremont, Wis.; Detroit College of Medicine and Surgery, 1895; aged 45; formerly a member of the State Medical Society of Wisconsin; died in the Theda Clark Hospital, Neenah, Wis., March 5, from tuberculosis of the intestines.

Claude Albert White, Memphis, Tenn.; Atlanta (Ga.) Medical College, 1880; aged 62; at one time a member of the Medical Association of Georgia; died at St. Joseph's Hospital, Memphis, February 20, from septicemia, due to an infected toe.

Darrell Jefferson Herron, Madrid, Ala.; Atlanta (Ga.) Medical College, 1884; aged 72; at one time a member of the Medical Association of the State of Alabama; died at the home of his daughter in Columbus, Ga., February 24, from pneumonia.

Hugh Frank Taylor ⊕ **Capt., M. C., U. S. Army,** Mintonville, Ky.; Kentucky School of Medicine, Louisville, 1893; aged 48; on duty at Camp Mills, N. Y.; died in the base hospital at that camp, December 18, from chronic diffuse nephritis.

Frank Wells ⊕ Boston; Harvard Medical School, 1868; aged 76; professor of histology in the College of Physicians and Surgeons, Boston; medical director of the John Hancock Mutual Life Insurance Company; died at his home, March 4.

Samuel Harold Boyd ⊕ **Lieut., M. C., U. S. Army,** Philadelphia; University of Pennsylvania, Philadelphia, 1913; aged 30; on duty at Camp Merritt, N. J.; died in the base hospital, Camp Merritt, December 24, from valvular heart disease.

Sylvester J. Hill, Fargo, N. D.; Homeopathic Hospital College, Cleveland, 1872; aged 72; a veteran of the Civil War, and department commander of the North Dakota Grand Army of the Republic in 1907; died at his home, March 1.

Bromwell Artemus Andrew, Jersey City, N. J.; Bellevue Hospital Medical College, 1869; aged 71; for several years surgeon of the Jersey City Police Department; died suddenly in his office, February 27, from heart disease.

Frank Underwood, Poplar, Mont.; University of Illinois, Chicago, 1905; aged 40; also a druggist; died at his home, February 27, from valvular heart disease.

Benjamin F. Carpenter, Belton, S. C.; University of Maryland, Baltimore, 1899; aged 40; died at his home, February 15, from pneumonia following influenza.

Henry Wilson, Newburgh, N. Y.; L.R.C.P. (Lond.) and L.R.C.S. (Eng.), 1879; aged 54; city manager of Newburgh; died at his home, February 26.

William Gibson Lumley, Detroit; University of the Victoria College, Coburg, Ont., 1870; aged 74; died at his home, February 24.

Richard Henry Sims, Powellton, Va.; Jefferson Medical College, 1867; aged 76; died at his home, February 21.

James Valentine Kern, New York City; Cornell University, New York City, 1902; died at his home, February 23.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

MISBRANDED NOSTRUMS

Chase's "Blood and Nerve Tablets," "Liver Tablets," and "Kidney Tablets."—Shipped in August, 1916, by K. E. Hafer,[1] trading as the Dr. Chase Co., Philadelphia. Analysis showed the "Blood and Nerve Tablets" to contain essentially, metallic iron, ferrous sulphate, sodium carbonate (washing soda), zinc phosphid, capsicum (red pepper), aloes, strychnin, and possibly gentian and podophyllum, with a trace of arsenic. The "Liver Tablets" were more than half sugar the active portion consisting of aloes, capsicum, licorice, ginger, and what appeared to be nux vomica. The "Kidney Tablets" were about 40 per cent. sugar, the active ingredients appearing to be methylene blue, licorice, and vegetable matter. The "Blood and Nerve Tablets" were falsely and fraudulently represented as a cure for weakness, nervous prostration, sexual exhaustion, anemia, etc. The "Liver Tablets" were falsely and fraudulently represented as a cure for paralysis of the bowels, diseases of the liver, dyspepsia, malaria, etc. The "Kidney Tablets" were falsely and fraudulently represented as a cure for paralysis of the bladder, general debility, rheumatism, Bright's disease in its early stages, dropsy, etc. Fine, $250.—[*Notice of Judgment No. 6170.*]

XXX Tonic Pills.—Shipped about January, 1917, by the XXX Pill Co., Lewiston, Me. Analysis showed the pills to contain a small amount of iron, a trace of quinin, strychnin, and resins, with emodin, aloin, gentian, anise oil, and vegetable extractives. Falsely and fraudulently represented as an effective treatment for diseases of women, sciatica, locomotor ataxia, St. Vitus' dance, paralysis, diphtheria, impotence, spermatorrhea, whooping cough, etc. Fine, $50.—[*Notice of Judgment No. 6189.*]

Egiuterro, Uicure, Sweet Rest for Children, Beaver Drops Comp., Blood Kleen, Heart and Nerve Regulator, Kidneyleine, Eye Powder, Tanrue Herbs and Pills, and 5 Herbs.—Shipped about June, 1916, by Albert G. Groblewski, Plymouth, Pa. Analysis showed "Egiuterro" to consist essentially of aloes, Epsom salt, jalap, strychnin, alcohol and water, flavored with methyl salicylate. "Uicure" consisted of five bottles, lettered "A" to "E," inclusive. "A" contained nearly 20 per cent. of alcohol, with aloes, Epsom salt and menthol. "B" contained alcohol, ammonia, chloroform, ether, oil of sassafras, menthol, benzoic acid, cinnamic acid, resins, and an unidentified alkaloid. "C" was essentially a water-alcohol solution of quinin sulphate and red pepper. "D" was essentially a water-alcohol solution of morphin, gum guaiac, ammonia, ammonium carbonate, and essential oils. "E" consisted of tablets containing lithium, sodium carbonate, salicylates, and salol. "Sweet Rest for Children" contained opium, alcohol, asafetida, magnesium carbonate, sugar and water. "Beaver Drops Comp." was a resin dissolved in alcohol and water. "Blood Kleen" appeared to be essentially a syrup containing over 13 per cent. alcohol, about 5 per cent. potassium iodid, sarsaparilla, licorice, plant extractives, with a small quantity of arsenic. "Heart and Nerve Regulator" contained alcohol, morphin, chloral hydrate, sodium bromid, valerianic acid, red pepper, glycerin, sugar and water. "Kidneyleine" was a water-alcohol solution of the acetates and nitrates of potassium and ammonium, with aromatics and indications of spartein. It contained over 23 per cent. of alcohol. "Eye Powder" was essentially iodoform and boric acid. "Tanrue Herbs and Pills" contained tansy, rue, pennyroyal, hepatica, sassafras, ginger, cinnamon, verbena and podophyllum. The pills contained licorice with indications of aloes. "5 Herbs" contained mistletoe, stramonium, skullcap, and black cohosh. All of these products were falsely and fraudulently represented: "Egiuterro" as a preventive of smallpox, and as a remedy for rheumatism, dyspepsia, all stomach disorders, coughs, headaches, etc.; "Uicure" as a cure for rheumatism, pyemia, sciatica, gout, etc.; "Sweet Rest for Children" as a remedy for three-months' colic, fretful, cross and nervous babies; "Beaver Drops Comp." as a remedy for irregular menses, etc.; "Blood Kleen" as a treatment for syphilis, eczema, anemia, cancer and lockjaw; "Heart and Nerve Regulator" as a heart and nerve regulator, a perfect sedative for delirium tremens, St. Vitus' dance, sleeplessness and nervous headache; "Kidneyleine" as a remedy for Bright's disease and dropsy; "Eye Powder" as a remedy for cataract and sore eyes; "Tanrue Herbs and Pills" as a remedy for suppressed, painful and irregular menses and "5 Herbs" as a remedy for epilepsy and "fits." Fine, $210.—[*Notice of Judgment No. 6178.*]

HAVENS' WONDERFUL DISCOVERY

Report of the Council on Pharmacy and Chemistry

The following report has been authorized for publication by the Council. W. A. Puckner, Secretary.

E. C. Havens, Sioux Falls, S. D., requested an examination of a remedy which he asserts he discovered for the cure of influenza. The labels of the specimens submitted read:

> "Prof. E. C. Havens'
> *Wonderful Discovery*
> INFLUENZA PREVENTIVE
>
> "Directions—Take ½ teaspoonful in wine glass of water not over twice a day for one week, then repeat every alternity week.
>
> "This remedy is good for Coughs, Colds, Lung Diseases, LaGrippe, Influenza, Rheumatism; good for Pains, Cramps, Backache, Lumbago, Neuralgia; for severe pains soak your feet in hot water for 3 nights, add 3 tablespoons of baking soda in water and apply Anti-Flue Medicine to the affected parts.
>
> "This is manufactured and sold by Prof. E. C. Havens, formerly of New York, branch office now located Main Ave. and 10th St., Sioux Falls, S. D. Official Rules of the Council on pharmacy and chemistry of the American Medical Association shall be complied with."

In response to a statement asking for the composition of the "remedy" and for evidence for the claimed curative virtues, Mr. Havens sent the following "formula" and testimonials:

Havens' Rheumatic Remedy

Oil Wintergreen	2 drams
Oil Sassafras	2 drams
Oil Black Pepper	2 drams
Spts. Camphor	1 dram
Spts. Turpentine	2 drams
Spts. Chloroform	1 dram
Tr. Arnica	1 dram
Tr. Opium (out)	1 dram
Alcohol	8 ounces

The following is typical of the testimonials:

> "Prof. Havens' Discovery for the cure of Influenza has, to my personal knowledge, done wonders for those who have used it. I personally know of several very severe cases which it has cured and of many cases which have been prevented by its use. I am taking the medicine as a preventative and can honestly say that I am glad of the opportunity of securing it.
>
> "I think the people should know more about this discovery during these times."

When inquiry was made if the formula for "Havens' Rheumatic Remedy" represented the composition of "Prof. E. C. Havens' Wonderful Discovery," and if the word "out" written after tincture of opium meant that this ingredient was not now a constituent of the preparation, Mr. Havens wrote:

> "In response to your letter of the 30th ult., beg to state that the Opium is not necessarily an ingredient in the compounding of this remedy, as it is difficult to obtain and I have eliminated its use.
>
> "This formula for Havens' Rheumatic Remedy is the same formula as is used in Prof. E. C. Havens' Wonderful Discovery. I discovered the virtues of the remedy in the treatment of Influenza by practical experience and hence the name 'Discovery.'"

The Council finds that E. C. Havens' Wonderful Discovery is an unscientific, irrational mixture, marketed under therapeutic claims which are unwarranted and without foundation. As the preparation is irrational and unscientific, the promise "Official Rules of the Council on Pharmacy and Chemistry of the American Medical Association shall be complied with" is obviously false.

---

[1] Hafer's fraudulent business was described in The Journal, May 25, 1918, and the matter is reprinted in the pamphlet "Medical Mail-Order Frauds," price 20 cents.

Correspondence

"GREEK ROOTS AND ENGLISH WORD FORMATION"

To the Editor:—Because errors are found in the Illustrated Medical Dictionary is no reason why the classical editor of The Journal of the American Medical Association should not be a purist. In the case of βρῶμα this lapse is peculiarly regrettable by reason of the use of this work in compounds referring to bromin, although the a comes from the second part of the compound, such as bromacetic, bromal, bromamide, bromalin, bromate and bromargyrite, all common terms in medicine. Webster's new unabridged, it is true, gives the word "bromatoxism," but calls attention to the fact that it is irregular. It gives also the regular forms of the compounds from βρῶμα (food), such as bromatography, bromatology and bromatologist. I beg to express the hope that in generous treatment of hybrid words our editor will not admit paesiatrics or pousphyllum.

H. W. Wiley, M.D., Washington, D. C.

[Comment.—We were at first slightly nettled to have such monstrosities as paesiatrics (pediatrics) and pousphyllum (podophyllum) thrust on us, by way of comparison, for we did not think the enormity of our own offense nearly so great. Where is the *locus classicus* for these monsters? Nor did we quite understand why they should be termed "hybrids," unless the good doctor would thereby indicate that in word formation, as well as in other forms of production, juxtaposition does not suffice—that there must be a coalescent union. Aside from this interpretation, we might state that by hybrid words one ordinarily designates such compounds as are formed from mixed elements, as from roots taken from two entirely distinct languages; for example, *Minneapolis*, the first part being Indian and the second part Greek; or *sub-way*, formed from a Latin and an English root.—Ed.]

"A NEW TREATMENT FOR THE MORPHIN HABIT"

To the Editor:—In his letter (The Journal, March 8, 1919, p. 747) discussing "A New Treatment for the Morphin Habit," Dr. Hugh McGuigan seems to be propounding the theory that there can be no immunity or tolerance unless Ehrlich's side-chain hypothesis is satisfied.

If laboratory men can demonstrate antibodies only with proteins, then they must admit the limitations of laboratory methods and not assail clinical facts. These facts are that immunity or tolerance can be established to nonprotein substances, and that human beings can take increasing amounts of alcohol, arsenic, atropin, cocain, morphin, etc. In the case of morphin, the new-born child of a morphinist mother shows tolerance, and may die if morphin is not administered.

But perhaps Dr. McGuigan has merely misunderstood my terminology when I wrote of immunity and antibodies. I used the terms in the broadest sense, and was not obsessed by any fixed ideas about Ehrlich's haptins of the first, second or third order.

Dr. W. B. Reed inquires (The Journal, March 8, 1919, p. 747) concerning the permanence of the cures. I regret that I can give no statistics on this point, but I have no reason to suppose that the percentage of relapses is different with the infusion treatment from other treatments. I believe that the permanence of the cure is determined chiefly by the patient's moral stamina.

C. S. Bluemel, M.D., Denver.

Dentistry and Cancer.—Cancer of the mouth in civilized countries has been greatly reduced by good dentistry. Eighty-five per cent. of the cancers of the lip occur in smokers. Formerly clay pipes, which became very hot, were much used, and there has been a notable reduction in the number of cancers of the lip since the clay pipe has gone out of fashion. Smoking, however, is the cause of most cancer of the lip, the tongue and the floor of the mouth.—Major W. J. Mayo, War Department Lectures.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

QUALIFICATIONS FOR THE PRACTICE OF MEDICINE IN BRAZIL

To the Editors—Can you give me any information regarding the practice of medicine or surgery in Rio de Janeiro, Brazil? Are there any opportunities open there, and what are the fees? Any other information will be appreciated.

H. H. S., M.D., Va.

Answer.—The requirements to qualify for the practice of medicine in Brazil are said to be almost prohibitive. An exception is made in favor of foreign physicians who have been connected with faculties of medical schools or who are authors of important medical books. Examinations for licensure are given in Portuguese, and interpreters are not allowed. The examination covers all the branches of the medical curriculum; fees amount to about $85. The applicant's diploma must be officially indorsed in the country where it is issued, and the signatures must be recognized by the minister of foreign affairs of Brazil. With the more friendly relations established with South American countries since the war, it is possible that restrictions against American physicians may be made less severe. We are unable to answer the query regarding opportunities.

BOOKS ON FOODS AND DIET

To the Editor:—I have been asked if I know where a book that contained the relative amounts of protein, carbohydrates and fats of foods could be purchased. The inquirer is a diabetic and is naturally interested to know just what kinds of foods he can partake of and just what to avoid. Will you kindly enlighten me?

Louis J. Wishnefsky, Chicago.

Answer.—The following books may be consulted:

Gephart-Lusk: Analysis and Cost of Ready-to-Serve Foods, Chicago, American Medical Association, 15 cents.
Hill and Eckman: The Starvation Treatment of Diabetes, Boston, W. M. Leonard, $1.
Lusk: Science of Nutrition, Philadelphia, W. B. Saunders Company, $4.50.
Tibbles: Dietetics, Philadelphia, Lea and Febiger, $4.

Possibly the first pamphlet will be the most appropriate in this case. Hill and Eckman's book is also very practical, and while small, covers the ground thoroughly.

REFERENCES FOR SKIN REACTION DIAGNOSIS

To the Editor:—Will you please send me available references for skin reaction diagnosis and subsequent treatment for asthma? I refer to the protein sensitization theories.

J. W. B., Illinois.

Answer.—You may refer to the following articles on the treatment of asthma:

Walker, I. C.: Treatment of Bronchial Asthma with Proteins, Arch. Int. Med. **22:** 466 (Oct.) 1918.
Sterling, A.: Results of Tests for Food Protein Sensitiveness in Small Groups of Asthmatics, Penn. M. J., December, 1918.
Cooke, R. A.: Protein Sensitization in Human with Reference to Hay Fever and Bronchial Asthma, Med. Clinics N. America, November, 1917.
Walker, S. C., and Wilkinson, J.: Comparison Between Cutaneous and Intradermal Tests in Hay Fever and Asthma, J. M. Res., November, 1917.
Rackemann, F. M.: Interesting Reactions Incidental to the Treatment of Two Cases of Bronchial Asthma, J. A. M. A. **69:** 889 (Sept. 15) 1917.

LITERATURE ON VOLUNTARY CONTROL OF PULSE RATE

To the Editor:—Will you please refer me to literature concerning the voluntary control of the pulse rate?

Charles H. Cargile, Bentonville, Ark.

Answer.—You may find the following what you want:

Favill, J., and White, P. D.: Voluntary Acceleration of Heart Beat, Heart **6:** 175, 1917.
West, H. F., and Lavage, W. E.: Voluntary Acceleration of Heart Beat, Arch. Int. Med. **22:** 290 (Sept.) 1918.
Voluntary Regulation of the Heart Beat, editorial, J. A. M. A. **70:** 1374 (May 11) 1918.
Voluntary Acceleration of Heart Beat, editorial, J. A. M. A. **71:** 1318 (Oct. 19) 1918.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ARIZONA: Phoenix, April 1. Sec., Dr. Allen H. Williams, 219 Goodrich Bldg., Phoenix.

COLORADO: Denver, April 1. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

DISTRICT OF COLUMBIA: Washington, April 9-11. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

FLORIDA (H): Jacksonville, April 8. Pres., Dr. Chas. W. Johnson, 33 E. Monroe St., Jacksonville.

IDAHO: Pocatello, April 1-2. Sec., Dr. Ray H. Fisher, Rigby.

IOWA: Iowa City, March 24-26. Sec., Dr. G. H. Sumner, Capitol Bldg., Des Moines.

MINNESOTA: Minneapolis, April 1-4. Sec., Dr. T. S. McDavitt, 741 Lowry Bldg., St. Paul.

MONTANA: Helena, April 1. Sec., Dr. S. A. Cooney, 205 Power Bldg., Helena.

NATIONAL BOARD OF MEDICAL EXAMINERS: Philadelphia, June 2-7. Sec., Dr. J. S. Rodman, 1310 Medical Arts Bldg., Philadelphia.

NEVADA: Carson City, May 5. Sec., Dr. S. L. Lee, Carson City.

NEW MEXICO: Sante Fe, April 14-15. Sec., Dr. W. E. Kaser, East Las Vegas.

OKLAHOMA: Oklahoma City, April 8-9. Sec., Dr. J. J. Williams, Weatherford.

RHODE ISLAND: Providence, April 3-4. Sec., Dr. B. U. Richards, State House, Providence.

UTAH: Salt Lake City, April 7-8. Sec., Dr. G. F. Harding, Templeton Bldg., Salt Lake City.

Texas November Examination

Dr. M. F. Bettencourt, secretary of the Texas State Board of Medical Examiners, reports the written examination held at Dallas, Nov. 19-21, 1918. The examination covered 12 subjects and included 120 questions. An average of 75 per cent. was required to pass. Of the 11 candidates examined, 10 passed and 1 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Southern College of Medicine and Surgery	(1914)*	75.9
Chicago College of Medicine and Surgery	(1914)	75
Tulane University	(1918)	90
Woman's Medical College of Pennsylvania	(1895)	75.4
University of Texas (1917) 86.3; (1918) 84.4, 86.6, 89.5, 98.1.		
National School of Medicine, Mexico	(1918)	79.4
FAILED		
Eclectic Medical University	(1918)	60

*Official reports do not show this candidate as a graduate of the institution named.

Pennsylvania January Examinations

Mr. Nathan C. Schaeffer, secretary of the Pennsylvania Bureau of Medical Education and Licensure, reports the oral and written examination held at Philadelphia, Jan. 7-11, 1919. The examinations covered 5 subjects and included 50 questions. An average of 75 per cent. was required to pass. Of the 49 candidates examined, 40 passed and 9 failed. The following colleges were represented:

College	Year Grad.	No. Licensed
PASSED		
University of Louisville	(1910)	1
Baltimore Medical College	(1909)	1
Maryland Medical College	(1900)	1
Boston University	(1912)	1
Hahnemann Med. Coll. and Hosp. of Phila.	(1916) (1917, 2)	3
Jefferson Med. Coll.	(1913) (1915) (1916, 2) (1917, 7)	11
Medico-Chirurgical College of Philadelphia	(1916)	1
Temple University	(1916) (1917, 4)	5
University of Pennsylvania	(1889) (1916) (1917, 8)	10
University of Pittsburgh	(1917)	2
Woman's Medical College of Pennsylvania	(1917)	3
University of Bombay	(1913)	1

FAILED	Year Grad.	Per Cent.
Chicago Homeopathic Medical College	(1902)	60
University of Louisville	(1917)	69.8
Washington University	(1905)	72
Western Reserve University	(1901)	69
Medico-Chirurgical College of Philadelphia	(1916)	73
Jefferson Medical College	(1917)	72.6
University of Pennsylvania	(1917)	69.8, 70.8
University of Kharkov	(1905)	39.2

Mr. Schaeffer also reports that 3 candidates were licensed through reciprocity from Jan. 23 to Feb. 13, 1919. The following colleges were represented:

College	Year Grad.	Reciprocity with
LICENSED THROUGH RECIPROCITY		
Western Reserve University	(1916)	Ohio
Jefferson Medical College	(1916)	N. Carolina
University of Pennsylvania	(1916)	Dist. Colum.

Book Notices

CONCERNING SOME HEADACHES AND EYE DISORDERS OF NASAL ORIGIN. By Greenfield Sluder, M.D., Clinical Professor and Director of the Department of Laryngology and Rhinology, Washington University Medical School, St. Louis. Cloth. Price, $7. Pp. 272, with 115 illustrations. St. Louis: C. V. Mosby Company, 1918.

The purpose of this remarkable book is, apparently, to record the present status of certain obscure but important subjects that have for many years undergone, and are still undergoing, investigations. It is an assembly to date of a work of research: a work that must stamp the investigator and his co-workers as scientists of a high order. Only pathologic conditions of the nose that are not common and are not well understood come under the author's view. Thus all frankly suppurative conditions of the paranasal cells are left out of the discussion. The subject-matter is made up of three main subjects, and these are supplemented by illustrative case histories.

"Vacuum frontal headaches," resulting from complete closure of the frontonasal duct, with or without active inflammatory processes, are, through diagnostic, anatomic and pathologic studies, placed seemingly on a foundation of quite clear understanding. The author speaks of six ways in which this duct may become occluded, and gives confidence by referring to a study of 580 cases.

The syndrome of nasal ganglion neurosis, a "neuralgic" headache syndrome of considerable definiteness and distinctiveness, is offered. The author dwells also on a secondary, less definite, syndrome, resulting, he thinks, from involvement of the sympathetic fibers of this ganglion, and including nasal coryzas, hyperesthesias and rhinorrheas, and indicating relationship to asthma and other distant disorders. This "sympathetic" factor is offered as one of importance, but with appropriate reserve. The sphenopalatine (nasal) ganglion is studied from all angles and the discussion on treatment includes injection of the ganglion with alcohol.

"Hyperplastic sphenoiditis" exists not alone in association with hyperplastic ethmoiditis but also as a separate disease of the sphenoidal region; this is one conclusion of the author's studies. The clinical bearing of certain types of headache, especially migraine, on sphenoidal disease is taken up. This involves an analytic study of the relationship of various nerve trunks to the sphenoidal cavity. Headaches, apparently dependent on a suppurating sphenoid, have sometimes failed to stop when all suppuration had ceased. Nevertheless the author was impressed with their probable local origin. And thus, with the aid of the micropathology of Dr. Jonathan Wright, he has been able to prove the presence of hyperplastic sphenoiditis even without any suppuration. This places the disease at the present time in the category of the extremely difficult, or even impossible, disorders, from the standpoint of diagnosis. We are under the necessity of revising and intensifying our diagnostic capabilities in the nasal region—that is, if nondischarging hyperplastic sphenoiditis as well as ethmoiditis is a reality and is important, as the author tells us it is. Inflammation within the sphenoid *may result in irritation or inflammation of the sphenopalatine* ganglion, but may also produce serious headaches and eye disturbance through affecting important nerve trunks in no direct manner related to that ganglion. Such disturbances are due, the author believes, to a hyperplastic bone process; and he believes that its mode of operation is to "narrow the bone canals through which the nerves pass."

The surgical aspect of the subjects treated are kept prominent, and surgical technic of the ethmoidal-sphenoidal region receives clear elucidation. The point of view is that of the nasal clinician, on whom the solution of the pathologic problems of this region naturally falls. The work is a rhinologist's work, so rich and varied in anatomic, diagnostic and operative information that rhinologists will hardly be fully educated without perusing it. The illustrations are numerous, varied, clear and useful. There is an extensive bibliography. In the presentation of such a complicated array of new information and new speculation, the text must necessarily sometimes become difficult to follow. Any possible additional means of systematizing the material would be advantageous to the reader. And a later edition might well be provided with more subheadings in the text, especially in the chapter on hyperplastic sphenoiditis. But, on the whole, the author is to be congratulated on the work accomplished.

The Human Machine and Industrial Efficiency. By Frederic S. Lee, Ph.D., LL.D., Dalton Professor of Physiology in Columbia University. Cloth. Price, $1.10 net. Pp. 119, with illustrations. New York: Longmans, Green and Co., 1918.

From the industrial point of view the human body is a machine capable of productive work, yet liable to breakdowns, wear and tear with resulting depreciation in value. The one striking difference between the human body and the ordinary machine is that the latter is inanimate. The human machine works according to laws of physics and of chemistry, to be sure, but the attempt to estimate its working power by mere mathematical formulas or by chemical equations is always more or less unsatisfying because there has to be reckoned with that mysterious something called life. And the problem of how to utilize the human machine in the most efficient manner has in it more than securing the employer's aim of a maximum output, or the laborer's desire of a maximum wage. For the worker must be viewed as a human being with a right not only to a living wage but enough to enable him to maintain his position as the head of a family and a self-respecting member of society.

These facts make the study of the worker in industry a complicated and difficult task in which economic and sociological questions are inextricably tangled. But underlying all these there is a physiologic problem involved. The worker has to be studied under varying conditions as to hours of labor, night work, overtime, rests, meals, speed of work, character of occupation, hygienic surroundings, home conditions, etc., all of which conditions have a direct physiologic connection with the problem. Fatigue, for instance, is an objective reality, not merely a subjective sensation of tire, and it influences output, may contribute to accidents, and therefore should be studied from a physiologic and not alone an economic standpoint.

No one in this country is better qualified than Professor Lee to speak authoritatively on this aspect of the subject. Many years ago Mosso did pioneer service along these lines. Miss Goldmarck sharply drew attention to the relation between fatigue and efficiency. Lee has carried on the same work patiently and persistently in laboratory and factory and on the platform, and has investigated and urged others to investigate the physiologic—or pathologic— problems of the laborer.

This small volume is an epitome, almost like a lawyer's brief, of the many topics associated with the laborer as an efficient machine in industry. Dr. Lee is broad-minded and catholic in his views, and does not give the impression of being partisan. He is alive also to the difficulties of the problem, and fully recognizes that conclusions must be cautiously drawn, all conditions for experiment carefully fixed, and that there must always be considered that uncertain and varying "human element" so hard to estimate at its true value, a point so well brought out by Phillip Sargent Florence.

There is a bibliography of ten pages and a good index. The book is written in a clear, entertaining style. As a guide for layman or physician who desires an outline of this timely subject or who wishes to be helped to pursue it still farther, it is of the greatest value.

Los Dèsarreglos Gastro Intestinales del Lactante. Por Dr. Luis Morquio, Profesor de Clinica Infantil, Montevideo. Paper. Pp. 540. Montevideo: Tipografia Moderna, 1918.

Morquio discusses the gastro-intestinal disturbances of infants, which he considers are a medical and social question of importance, not only on account of their undue prevalence but also because they can be prevented. He bases his statement on twenty-five years of experience, both in private practice and in teaching the subject at the University of Montevideo. His book has naturally been prepared to meet the special needs of Uruguay, using for purposes of comparison the data from other countries. The book, from that standpoint, is rather exhaustive as Morquio has attempted to review in various chapters the data that exist in foreign literatures. Naturally he places particular stress on the importance of breast feeding, and incidentally lays stress on the protection of the mother, which he considers of great importance for the child, quoting in this respect Pinard's phrase: "Il faut d'abord, et ensuite et toujours protéger la mère" (the mother must be protected first, last and always).

The outsider will find of special interest the discussion of infant mortality in Uruguay, which Morquio places in the decade 1906-1915 at 50,000 children below the age of 2 years, that is, 5,000 a year, and half of which he estimates could be avoided. He invites attention to the fact that in Montevideo the mortality has actually increased during the five-year period 1910-1914, coinciding with the establishment of infant dispensaries and milk stations, although the coincidence may be merely casual. Specific measures are recommended to deal with this problem in Uruguay.

Social Medicine, Medical Economics and Miscellany

The 1916 Epidemic of Poliomyelitis

In Public Health Bulletin 91 of the Treasury Department, United States Public Health Service, C. H. Lavinder, A. W. Freeman and W. H. Frost have reported the results of their study of the 1916 epidemic of poliomyelitis in New York City and the Northeastern United States, including the whole of New England, the Middle Atlantic states, Delaware, Maryland and the District of Columbia. The report treats separately of the epidemic in Greater New York, with nearly 9,000 cases, and in the outside area comprising the states named, including New York State, with nearly 12,000 cases. In each area a general epidemiologic study was made, and in certain of the districts also an intensive epidemiologic study. The information gathered is analyzed, tabulated and represented in graphic charts, and covers every aspect of the subject. In this outbreak, the greatest in numbers and intensity that has ever been reported, with a high fatality rate, the epidemiologic features are quite similar to those of other epidemics that have been studied. There is nothing peculiar or unique either in seasonal incidence, age, distribution, comparative fatality rates at different ages, or in special conditions, such as environmental surroundings, source of milk and water supplies, occupation, prevalence of insects, or presence of animals, to which could be attributed any influence on the occurrence of the disease. There is also the usual lack of evidence as to contact relationships between cases of the disease. Any idea of a new or powerful strain of the virus is open to doubt, as far as New York City is concerned. The disease is endemic in that city, and the origin in this epidemic was quite possibly indigenous. The development of endemic diseases into epidemic proportions is a common observation, the reasons for which are still unknown. One of the notable features of the epidemic was the definite geographic focus in Brooklyn, and the striking uniformity of its spread both in rate and intensity from this point. Plotted curves of the rise and decline of the disease would seem to indicate that it spread by constantly multiplying foci of infection. As for the epidemic outside the city of New York, it may perhaps be accounted for much on the same grounds, the endemic presence of the disease, with the sudden extension to epidemic proportions for the same unknown reasons that apply to these phenomena. An interesting part of the study was the attempt to trace the relations of the New York City epidemic to the occurrence of cases in neighboring cities and the adjacent country. It was possible to trace a number of cases whose source of infection was probably in New York, and in a small number of cases almost certainly in that city, as these were the first cases occurring in the communities to which the patients had recently migrated from New York City. The report offers the conclusion, however, that the study does not show that the cases actually in persons from New York City were a very large factor in the spread of the epidemic, since such known cases were the first known source of infection in only 9 per cent. of the infected towns, and constituted only 1.4 per cent. of the cases that occurred in the states included. Interesting also is the finding that the development of cases in persons going out from New York City was quite irregular; but in a large proportion of those probably definitely infected before leaving the city, the disease developed within seven days after their exodus.

Eugenic Marriage

The *British Medical Journal*, February 8, thus summarizes the new Norwegian marriage law, which came into force, January 1: A man under 20 and a woman under 18 may not marry without the consent of the authorities. Birth and baptism certificates must be produced before the bans are published. Under certain conditions one or both of the parties may be required to show that they have not been insane. Both must declare in writing that they are not suffering from epilepsy, leprosy, syphilis or other venereal disease in an infectious form. In the other alternative, the subject of these diseases must prove that the other party to the marriage contract is cognizant of the fact, and that both parties have been instructed by a physician as to the dangers of the disease in question. The physician is not to be tied by professional secrecy and is bound to interfere if he knows that any one of these diseases is being concealed by either side. A written declaration must also be given by the parties as to previous marriages and to children born to them out of wedlock. The marriage may be nullified if it is afterward proved that insanity or any of the foregoing diseases has been concealed, or if an incurable morbid condition incompatible with married life exists. Dissolution of the marriage may also be claimed if false declarations have been made or obstacles concealed. If the woman has become pregnant by another man, or if the man has rendered another woman pregnant and this has not been revealed, dissolution of the marriage may be claimed, whether the child of this irregular union be born before or after the marriage; such a claim must be made within six months of the facts becoming known to the claimant. Many other causes are defined as valid for the dissolution of the marriage.

Antivenereal Disease Legislation in Sweden

The Swedish law of June 20, 1918, provides that every one suffering from a sexual disease is obliged to apply for treatment to some physician and to follow the directions of the latter. Hospital treatment and medicines are also free. The physicians are obliged to assume the treatment. Large cities can appoint physicians for the purpose; if more than one physician is appointed, one of them at least must be a woman. Cities of more than 20,000 inhabitants must provide a policlinic in charge of specialists, but there must be nothing to show what the diseases are that are being treated there. The law provides further for a physician to be sent at state expense to remote points when it is learned that sexual disease occurs there. The physicians must enlighten the sick or their parents or guardians in regard to the nature of the disease, the danger for others and the necessity for refraining from marriage, in accordance with a circular which is supplied by the authorities, unless circumstances render this information perilous for the patient. Refractory or negligent patients must be denounced to the public health authorities; also the source of the infection, as to which the physician must enquire. The person denounced as the source of infection must appear before the public health authority (gezondsheid-inspecteur) or send him a certificate to the effect that he or she is healthy or is taking treatment. He or she can be compelled to enter a hospital for treatment, as also refractory or negligent patients with venereal diseases. If a person with venereal disease in a contagious phase is betrothed, the minister or priest concerned is informed so that he can prevent the marriage. If the local public health authority is not obeyed, then the higher officers will interfere with the help of the police. The patients have the right of appeal to the king against the measures imposed, but pending the appeal the measures will not be relaxed. All measures will be kept strictly secret from the outside world. The law abolishes regulation of prostitution. The *Nederlandsch Tijdschrift* from which we translate the foregoing credits it in turn to the *Münchener medizinische Wochenschrift.*

Federal Court Not Concerned with Vaccination Case

(Gillin v. Board of Public Education of City of Philadelphia et al. (U. S.), 250 Fed. R. 649)

The United States District Court, Eastern District of Pennsylvania, dismisses for want of equity, and with costs to the defendants, the bill of complaint in this case, wherein the plaintiff sought in a federal court relief from the laws and decisions of the courts of Pennsylvania because, having refused to have his children vaccinated as required, they were denied admission to the public schools and he was convicted of having violated the state law requiring parents to send their children to school. The court says that counsel for the plaintiff was widely known to have given much thought to this legislation and to be familiar with its subject-matter in all its features, and the argument addressed to the court was earnest and exhaustive of all that was worth being urged in argument. The general situation was thus presented: Part of the legislation in question has for its object the requirement of a school education. Resistance to its commands invites the imposition of a penalty. Another part of such legislation has for its motive the preservation of the public health by the requirement of vaccination, thus preventing the spread of infectious diseases. The latter provision has no penal sanction. The provision, however, is that unvaccinated pupils may be denied admission to the public schools. The predicament is thus presented: A parent (the plaintiff) refuses to send his children to a school. He thereby incurs a penalty. He refuses to subject them to vaccination. He thereby incurs no penalty. The same parent (the plaintiff) sends his children to school. They are unvaccinated, and admission is denied them. The parent, not having sent them to a school, is then subjected to the penalty. The plaintiff complained of this as the imposition of a penalty for his refusal to comply with the vaccination requirement, which carries no penalty.

It is to be first observed that all the law that was involved (at least primarily) was state law. The person to whom the law might be held to apply was a citizen of the state, the authority and meaning of the laws of which were involved. No federal question was raised, nor has a federal court (in this presentation of the question) jurisdiction of the subject-matter. Jurisdiction was asserted only by virtue of the fourteenth amendment to the Constitution of the United States, which prohibits states from depriving citizens of life, liberty or property, without due process of law. Through his right to "due process of law," the plaintiff had the right to have the state tribunals pass on his defense, and to have the case conducted through all its appellate stages until it reached the highest court of the state, and, if any federal, constitutional or other question was involved, to carry it to the Supreme Court of the United States. There was no complaint of a denial of this right. His real complaint was that he was charged with noncompliance with the requirements of the laws of the state, and that the statutory penalty was imposed by a magistrate. From this judgment he appealed to the proper court sitting for the county. That court affirmed the judgment. From this he appealed to the superior court, with a like result. He then made his appeal to the supreme court of the state, and the

84, or 87.5 per cent., of the patients are living, and 12, or 12.5 per cent., are dead. Of the 24 far advanced cases, 13, or 54.25 per cent., are living and 11, or 45.75 per cent., have died. There were 119 doubtful cases, with 112, or 94.1 per cent., living and 7, or 5:9 per cent., dead, 5 of the 7 patients having died from causes other than tuberculosis. During four years in 1,229 of the 1,654 cases tubercle bacilli were found in the sputum. This was 74.3 per cent. of all cases. Four hundred and thirteen, or 33.6 per cent., are living and 816, or 66.4 per cent., are dead. Eighty-four were incipient, with 62 living and 22 dead. There were in all 495 moderately advanced cases with bacilli in the sputum, of which 259, or 52.3 per cent., are living, and 236, or 47.7 per cent., are dead. Of 650 far advanced cases, 92, or 14.2 per cent., are living, and 558, or 85.2 per cent., are dead.

Subsequent History of Arequipa Patients.—Brown has found that tuberculin, properly used, is a valuable if not indispensable remedy in about 10 per cent. of cases of tuberculosis and that it might be used with advantage as a supplementary safeguard in a much larger number whose immunity is probably sufficient by only a narrow margin. At Arequipa the use of tuberculin has been restricted to patients whose condition and rate of improvement at the sanatorium were not satisfactory, and this has applied to cases in all stages. When the rest on bed and correction of all other physical conditions result in no clinically measurable evidence of improvement after a month of observation, they introduce tuberculin as the only new variable, continuing everything else as before. If a patient ceases to improve before attaining her normal, after a gain however slow, tuberculin is tried. In this way it is possible to judge whether tuberculin is really responsible for a change for the better. In the initial period of correction of underlying conditions extensive use is made of iron and arsenic preparations by hypodermic injection with great benefit. Every chance is given the patient to show her own recuperative ability without its stimulation by tuberculin. Sixty-eight per cent. of patients in the first stage have been back at work from one to five years and are still well.

- Bearing of War Neuroses on Immigration. L. Kolb, Ellis Island.—p. 317.

Intravenous use of Arsphenamin in Syphilis of Nervous System.—In general paresis and in tabes the chief lesions are within the substance of the brain or of the cord far removed from actual contact with the cerebrospinal fluid. Therefore, it is almost impossible to bring the spirocheticidal remedy into immediate contact with the foci of disease unless these remedies can be introduced through the blood streams. Sachs calls attention to the fact that it is only in the earliest stages of tabes dorsalis that the disease involves the meninges and spinal ganglions; later on it sets up marked degenerative changes in the spinal tissue, and these secondary changes are entirely beyond the reach of the cerebrospinal fluid and its contents. In the remaining meningo-encephalitic and meningomyelitic processes of specific origin, more or less exudative in character, it might be supposed that spirocheticidal substances introduced into the cerebrospinal fluid might have an active therapeutic effect, if such substances could course freely in the cerebrospinal fluid and if it could be shown that they were retained in this fluid for any satisfactory period of time. It has been shown, however, that the cerebrospinal fluid circulates imperfectly and there is very little absorption of this fluid by the cortical or spinal cells. Hence, however attractive the intraspinal medication has appeared to be, it is essentially useless and theoretically unsound. Sachs has obtained most satisfactory results from intravenous injections administered on alternate days for a period of three to four weeks according to the symptoms presented by the patient, and then allowing a period of complete rest or giving weekly or semiweekly injections of mercuric salicylate for a period of four to six weeks and then again starting in with the same course of arsphenamin injections. Some patients have received as many as forty or fifty intravenous injections within a period of a year or eighteen months.

Path of Invasion of Brain in General Paresis.—Observations were made by Orton on the larger cranial vessels before they enter the brain mass in material taken from nine cases of paresis. The lesions encountered fall into two groups: (1) those in which the process is evidently stationary, and (2) those showing evidence of progressive chronic inflammation. The stationary lesions are comparable in every respect to those of healed syphilitic endarteritis. The active chronic inflammatory lesions consist in a lymphocyte and plasma cell exudate in the perivascular connective tissue sheath—the adventitia—which is quite comparable with that of the vessels within the brain substance, although the plasma cells are a little less numerous and apparently do not tend to mass together into the mosaics seen around many smaller arterioles in the cortex. Such exudates were observed in eight of the nine cases. In one case, in addition to this cellular infiltration, one very small vessel traveling in the adventitia of the carotid in the neck showed the reduplicated succulent swollen endothelial cells which are found in acute stages of syphilitic endarteritis.

Association of Syphilis of Nervous System and Cardiovascular Syphilis.—Among 125 cases of syphilis of the central nervous system seen by Friedman there were nineteen cases of cardiovascular disease—an incidence of 14 per cent. Of these, thirteen showed disease of the aortic valve either alone or in combination with aneurysm or dilatation of the aortic arch. There were two cases of myocardial degeneration with resulting decomposition. Two showed typical aneurysms without demonstrable disease of the aortic valve. In the series was one carotid aneurysm, and one patient showed the clinical picture of premature atherosclerosis with probable occlusion of mesenteric vessels.

Salt Solution Intravenously in Dementia Praecox.—In ten cases of dementia praecox Miller administered intravenous injections of 0.9 per cent. salt solution made in freshly distilled water. The sodium chlorid used was free from sulphates, alkaline earths and heavy metals, magnesium, iodids, potassium, iron and ammonium. Intravenous injections were made by the gravity method. The initial dose was 3 c.c. per kilogram of body weight. Each succeeding dose was increased by 30 c.c. and injections were made at seven-day intervals for a period of four and one-half months. Seven of the ten patients showed no mental improvement; of the remaining three, two brightened up slightly, the third brightened up enough to work. Eight of the ten patients gained in weight from 2 to 15 pounds; one patient lost 1 pound and one patient remained stationary. The blood of twenty-five patients was examined for chlorin content and in none was there a deficiency.

Acutely Inflamed Peripheral Tissue.—The experiments set forth by Segàle establish the fact that the heat of the inflamed part has its origin primarily in the local biochemical activity of the cellular elements which participate in the inflammatory process. The inflammatory hyperemia, instead of being the necessary and constant source of the inflammation must be considered a natural physiologic compensation for the abnormal local calorification. The rapid circulation of the blood in the inflamed part tends to moderate the increase in local temperature and to equalize the temperature with that of other parts of the body.

Bacillus Influenzae in Throats and Saliva.—Pritchett and Stillman report facts obtained during an investigation of the bacteriology of influenza which included (1) the use of oleate hemoglobin agar, (2) the incidence of *B. influenzae* in uncomplicated and complicated cases of influenza and the associated types of pneumococci, (3) the occurrence of *B. influenzae* in convalescents, and (4) the occurrence of *B. influenzae* in the mouth secretions or throats of normal people. The medium used in this work was Avery's oleate hemoglobin agar. *B. influenzae* was cultivated from the mouth of 93 per cent. of cases of influenza and bronchopneumonia. It was present in the mouths of 43 per cent. of normal individuals. The types of pneumococci found associated with the complicating bronchopneumonias of influenza were the types usually found in normal mouths.

Life of Transfused Blood Corpuscles.—Ashby claims that the life of the transfused corpuscle is long; it was found to extend for thirty days and more. Therefore, beneficial results of transfusion are not due primarily to a stimulating effect on the bone marrow, but to the functioning of the transfused blood corpuscles.

Specific Antiserums for Infections of Unknown Cause.—The results obtained by Rous and others would seem to indicate for the absorption method some usefulness in the study of immunity to infections of unknown cause. By the method of selective absorption with tissue, protective serum antibodies have been demonstrated by Rous and his associates in the case of an infection of unknown cause; namely, a chicken sarcoma transmitted by a filtrable agent. Geese were repeatedly injected with the finely ground sarcoma and with blood from fowls moribund of it; and their serum acquired the power to prevent the tumor-producing agent from causing growths. That this was not due to antibodies elicited by the chicken tissue as such was shown by exhaustion of the goose serum with chicken red cells, a step which had not the least effect on the tumor-preventing power, and also by experiments with rabbits immunized as were the geese. These animals developed strong chicken antibodies in their serum which failed nevertheless to affect the tumor-producing agent.

Bristow Coil and Treatment by Graduated Muscle Contraction.—Attention is directed to a method of physical therapy which is as yet but little known in this country and which comes from the war practice of our English allies with the assurance of a considerable usefulness. The fundamental idea of this method lies in the ability to stimulate the damaged muscles to contraction by an induced current in such a way that this may be exactly graduated both as regards degree and rhythm. One may begin with contraction of minimal intensity and very slow rhythm and proceed to increase in both regards according to the functional response which is thereby obtained. The method also has the very great advantage of enabling one to limit stimulation very nearly to a particular muscle or group of muscles and to an extent not possible with the older methods. The current which is yielded by the Bristow coil differs from that of the usual faradic coil only in so far as it may be used in very great intensity without producing pain and, as stated, with the opportunity of quite definitely regulating and graduating the dosage from treatment to treatment and from case to case, as well. No effect is attributed to the electricity as such, except as it is used as the means by which the muscle is made to contract to the desirable degree and frequency.

Sprains of Knee Joint.—Harding urges aspirating any distended joint promptly, since practically all effusions are bloody and absorb slowly. They lead to the formation of a thickened, chronic joint. Distention of the capsule must be prevented, as it is one of the main causes of a weakened knee in after life. Early baking and massage and strict supervision of the manner of returning to use are likewise important.

The papers by Clark, Frazier, Davis, Flexner and Sweeney were abstracted in THE JOURNAL, October 5, pp. 1164 and 1165.

Chorea Etiology.—The case reported by Graves and Paige offers several interesting features. Apparently, a typical acute chorea made its appearance synchronously with acute infection. The spinal fluid was negative for bacteria, syphilitic antibody and globulin, but was under pressure. Associated with the chorea was acute endocarditis and lobular pneumonia with marked toxic lesions in nearly all the parenchymatous organs. The postmortem Wassermann was negative. Histologically the brain was negative.

- *Iodin Urine Test for Acidosis. C. Mitchell, Chicago.—p. 404.

Theory of Asthma.—The underlying cause of asthma according to Knapp is the overproduction of irritating gases in the gastro-intestinal canal, which, operating physically and chemically, produce the asthmatic paroxysm. 1. Physically, by overdistention of abdomen and of the pressure upward of the diaphragm against the lungs, whose expansion is violently interfered with. 2. Chemically, by irritating the esophagus and pharynx, which irritation the patient attempts to clear away by the act of coughing. So long as the irritation continues, so long continues the ineffective coughing. The longer the irritation continues, the more violent becomes the act of coughing, the consequence of which is dilatation of the pulmonary air vesicles, which may and often does terminate in emphysema of the lungs. The asthmatic paroxysm ends when the irritation in the esophagus and pharynx have been removed, partly by neutralization of the irritation and partly by its dilution with pharyngo-esophageal secretions.

Iodin Urine Test for Acidosis.—An iodin test for acidosis has been devised by Mitchell which he claims can be used quantitatively. The best way to apply the test is the following: To 145 c.c. of water (hydrant water will do) are added 3 c.c. of Lugol's solution and 2 c.c. of a saturated solution of picric acid, the whole being thoroughly mixed. The result is a fine clear reddish liquid of bright color. Pour this liquid into a white dish and heat it on the water bath to a temperature of 180 F., but if a water bath is not available it may be heated over the flame until fumes are abundantly given off, boiling being avoided by turning down the flame sufficiently. When thus heated, the urine is added as quickly as possible but in small amounts at a time, using for this purpose a graduated buret. If, however, a buret is not available, a small graduate or graduated bottle may be used from which to pour the urine into the hot liquid. In acidosis the amount of urine needed to turn the bright red color to a bright yellow color is small, and the smaller the worse the case. In severe cases 2 or 3 c.c. of urine will almost immediately discharge the red color. In cases of moderate severity 8 or 10 c.c. may be required. Normal urines do not usually affect the color in smaller amounts than 15 c.c., except possibly in unusual conditions of concentration, where the amount of urine in twenty-four hours may be but a few hundred cubic centimeters. In most cases of normal urine, of specific gravity ranging from 1.015 to 1.020, the amount of urine required to effect change from red to yellow is around 20 c.c., or even higher, as high as 50 c.c. in some cases.

Standardized Rest in Tuberculosis.—Prolonged rest in bed in the treatment of phthisis pulmonalis is advocated by Thompson because he believes that exercise has no place in the treatment of a tuberculous lesion, regardless of its location. The final results of treatment in most tuberculosis sanatoria are disappointing. Permitting the patient to go on exercise before he is ready for it is the most common cause in curable cases. Immobilization in bed stops absorption; septic symptoms disappear, the patient gets fat. He should be kept quiet till scar tissue is formed and healing is well established.

Malaria Control Demonstration.—The effectiveness and practicability of measures directed exclusively against the propagation of mosquitoes as a means of controlling malaria in towns, was further demonstrated during 1917 by operations carried on in Hamburg, Ark. The work was conducted by the International Health Board in connection with the United States Public Health Service and the Arkansas State Board of Health. Taylor describes what was done.

Foreign Bodies in Air and Food Passages.—Jackson analyzes 628 cases in which he removed a foreign body from either the lungs or the esophagus. Taking together all deaths from any cause whatever within one month after endoscopy, the mortality has been 1.9 per cent. Of the twenty-three cases in which the foreign body had been present for periods ranging from two months to twenty six years, all of the patients recovered perfect health except two. One of the two died after removal of a nail that had been in the lung for four years. The symptoms pointed to embolism of the middle meningeal artery. The child was known to have an endocardial lesion secondary to the septic pulmonary focus; but whether the embolus was from this or from the primary infective focus in the lung could not be determined (4). The other patient died of some thoracic or abdominal condition of sudden onset, the nature of which could not be determined.

Blood Transfusion.—A series of 1,036 transfusions performed on 429 patients are recorded by Pemberton. Five were done by means of the paraffin-lined cylinder, thirty by a modified cannula-syringe technic, and the other 1,001 by the citrate method. The cases are grouped according to indications for transfusion: Primary (pernicious) anemia, 657 transfusions in 185 cases. Secondary anemia, 243 transfusions in 149 cases. Bleeding, 81 transfusions in 59 cases. Acute toxic and septic conditions, 34 transfusions in 25 cases. Leukemias, 20 transfusions in 10 cases. Shock, 1 transfusion in 1 case. In 219 transfusions (21 per cent.) of the series, there occurred from fifteen minutes to one hour later a slight reaction of chill and fever, a temperature of 100 to 105 F., with or without malaise, headache, nausea and vomiting and diarrhea, and followed, in a small percentage of cases, on the third day after the transfusion, by an eruption of herpes. In another 15 per cent. of transfusions there occurred a rise of temperature to 100 F. or above, not associated with chill and nausea. These were, in every instance, of a transitory nature, the temperature returning to normal in from twelve to thirty hours, and in only two instances was it at all probable that the good of the transfusion was vitiated by this complication.

These reactions occur early after the introduction of 50 or 100 cubic centimeters of blood; the patient first complaining of tingling pains shooting over the body, and a fulness in the head and an oppressive feeling about the percordium, and, later, an excruciating pain localized in the lumbar region. Slowly but perceptibly the face becomes suffused, a dark red to a cyanotic hue; respiration becomes somewhat labored, and the pulse rate, at first slow, sometimes suddenly drops as many as 20 to 30 beats a minute. The patient may lose consciousness for a few minutes. In one half of the cases an urticarial eruption, generalized over the body or limited to the face, appeared along with these symptoms. Later, the pulse may become very rapid and thready; the skin becomes cold and clammy, and the patient's condition is grave. In from fifteen minutes to an hour, a chill occurs, followed by high fever, a temperature of 103 to 105 F., in which the patient may become delirious. Jaundice may appear later. The macroscopic appearance of hemoglobinuria is almost constant. In three such instances the symptoms were not recognized at the time of the transfusion, and 500 cubic centimeters of blood were injected. All the patients died, two in one and three hours, respectively, following the transfusion, and one became comatose shortly afterward and died thirty hours later. In the other nine instances the symptoms were early recognized and interpreted, and the transfusion was concluded after the injection of 50 to 100 cubic centimeters of blood. Epinephrin and atropin were administered with good effect. There was no mortality in this group.

The cases point out most strikingly the fact that the injection of incompatible blood, namely, in which the donor's cells are agglutinable by the serum of the patient, is attended by the development of symptoms of the gravest nature, and that if these are not early recognized and the transfusion concluded before the injection of a large quantity of blood, fatal results are to be expected.

Cutaneous Neoplasms.—Cutaneous neoplasms are divided into three groups by Van Beuren: (1) those on the skin; (2) those in the skin, and (3) those beneath the skin. He advises that every new growth of the skin should be excised as soon as one can decide that it is a new growth. That if any suspicion of present malignancy is entertained and local excision is thought adequate, a much wider incision of the tumor should be planned than has commonly been practiced in the past.

Postoperative Pneumonitis.—At the New York Presbyterian Hospital during 1917, out of 1,940 operations there were sixty-five cases of postoperative pneumonia, a morbidity percentage of 3.3. Cleveland found that amount the predisposing factors of postoperative pneumonia are: (*a*) coughs, colds, etc., previous to or on admission to the hospital; exposure to cold while in the hospital; (*b*) condition of the patient; (*c*) type of operation; (*d*) anesthesia. Eighty-six per cent. of the operations performed in this series were celiotomies, and a majority of these were of a relatively simple nature, such as hernia repair and removal of simple appendix. Although the gas-ether sequence, closed method, anesthesia was followed by forty-four cases, Cleveland points out that the anesthetic per se does not cause the pneumonia, a statement which is no longer doubted. The irritation of the anesthetic does, however, prepare the way for organisms already present in the upper respiratory tract by lowering the resistance of the lung tissue. Roentgenography was employed as an aid to diagnosis in fifty-six out of sixty-five cases.

There were seven deaths in the sixty-five patients, making the mortality 10.7 per cent. No one of these occurred where the pneumonia was the only complication; in other words, no otherwise healthy patient undergoing operation died as a result of his pneumonia. Malignancy claimed three patients. one with carcinoma of the colon, another with carcinoma of the esophagus and a third with carcinoma of the cystic duct. All of these were in very poor condition. A pulmonary embolus caused one death. Another patient died in a diabetic coma following incision and drainage of an alveolar abscess. A mastectomy in a patient 65 years of age, not in very good condition, resulted in a fatal pneumonia. The seventh patient died of inanition following a duodenal fistula rather than from the pneumonia. Two other patients died in the hospital; one, a paraplegia with a positive blood culture, died of sepsis six weeks after the embolic pneumonia had subsided; the other died over a month after his pneumonia and from no associated condition.

Omentopexy in Cirrhosis of Liver.—Omentopexy was done in twenty-three cases of cirrhosis of the liver. Eighteen cases were due to excessive use of alcohol; two to syphilis; cause unknown in one case and in two the ascites was associated with an enlarged liver secondary to cardiovascular disease. In one of these last-mentioned cases the patient died of acute cardiac dilatation directly after the operation. The other, three years after operation, is still alive and greatly improved.

Incompetency of Ureterovesical Valves.—Hepburn reports a case which he believes supports the theory of inflammatory infiltration as a cause of ureterovesical valvular incompetency; the inflammation apparently started in the bladder instead of in the kidneys.

Operation for Production of Sterility.—Cupler divides the tube and turns back a peritoneal cuff on the proximal end. The denuded muscle and mocosa are crushed in the bite of an angiotribe. A catgut ligature is applied in the crease, the cuff is brought over and a ligature is applied. The distal end of the tube is ligated, and both ends approximated and the rent in the broad ligament is closed.

Excluding Septic End of Bowel During Intestinal Resection.—Farr turns a rubber glove inside out over the divided bowel, this keeping it out of the field.

Peritoneal Drainage.—Heald uses a double caliber glass tube with movable gauze wick. The double tube is one-half inch in (outside) diameter. The lower end is closed, except for an oval opening one-eighth inch from the lower end on each side, and a small opening in the bottom. The longitudinal septum extends to one-fourth inch from the lower end. One end of a gauze wick, 1 inch wide and several yards long, is inserted in the upper end of one "barrel," and is pushed down its lumen to the lower end with a small probe, pulled out of the opening in the bottom, the end is reinserted through this opening and pushed up through the other "barrel," passing around the smooth lower end of the septum. The tube, threaded with the wick, is inserted to the bottom of the cavity, and the wound is closed completely around it. The tube should be long enough to project above the dressings, which are covered and protected by a sheet of rubber dam, through a small stretched opening in which the tube has been passed previously. The roll of sterile gauze wick in a cloth bag is pinned outside the dressings and covered with a sterile towel. During the first twenty-four hours, at more or less frequent intervals, depending on the quantity of purulent secretion, the nurse, with sterile gloved hands, steadies the tube with one hands, pulls the wick through with the other until it comes through dry, cuts off and removes the soiled portion, and replaces the sterile towel, without having disturbed the patient. After twenty-four hours the tube, having served its purpose, is removed, and replaced by a small "cigaret," or by any form of drain the surgeon may prefer. The method is used in the drainage of any cavity where dependent drainage is impracticable, but in peritoneal infections from perforations, it will probably be found most useful.

Inguinal Herniotomy.—Pitzman's suggestion in technic is simply to insert the mattress sutures for the repair of the abdominal wall, while the peritoneal cavity is still open.

Pathogenesis of Deficiency Disease.—The conclusions reached by McCarrison as a result of his clinical, anatomic, histologic and bacteriologic observations may be summarized as follows: The absence of certain accessory food factors from the dietary—improperly termed "antineuritic"—leads not only to functional and degenerative changes in the central nervous system, but to similar changes in every organ and tissue of the body. The morbid state to which their absence gives rise is not a neuritis. The symptom complex resulting from the absence of these substances is due (a) to a chronic inanition; (b) to derangement of function of the organs of digestion and assimilation; (c) to disordered endocrine function; (d) to malnutrition of the nervous system, and (e) to hypersuprarenalinemia. Certain organs undergo hypertrophy; others atrophy. Edema has invariably (100 per cent.) been associated with great hypertrophy of the suprarenal glands, while 85 per cent. of all patients having great amount of epinephrin in such patients as determined by physiologic methods, has been considerably in excess of that found in cases not presenting this symptom, and greatly in excess of that found in normal suprarenals. Inanition gives rise to a similar state of suprarenal hypertrophy, and to a similar state of atrophy of other organs, the brain excepted. The edema of inanition and of beriberi is believed to be initiated by the increased intracapillary pressure which results from the increased production of epinephrin, acting in association with malnutrition of the tissues. Gastric, intestinal, biliary and pancreatic insufficiency are important consequences of a dietary too rich in starch and too poor in "vitamines" and other essential constituents of food.

It is suggested by McCarrison that some of the obscure metabolic disorders of childhood might be examined from this viewpoint as well as from that of endocrine gland starvation. A state of acidosis results from the absence of so-called "antineuritic vitamins." Great atrophy of muscular tissue results from deficiency of accessory food factors. Profound atrophy of the reproductive organs is an important consequence of the "vitaminic" deficiency. The central nervous system atrophies little: paralytic symptoms, when they occur, are due mainly to impaired functional activity of nerve cells; much more rarely to their degeneration. It is thought that, because of their atrophy out of all proportion to other tissues, the thymus, the testicles, the ovary and the spleen provide a reserve of accessory food factors for use on occasions of metabolic stress. This reserve, however, is rapidly exhausted. The bones are thinned, and there is a loss of bone marrow. The red cells of the blood are diminished by about 20 per cent. The whole morbid process is believed to be the result of nuclear starvation of all tissue cells. Infections and parasitic agencies are often important causes in determining the onset of symptoms. "Vitaminic" deficiency renders the body very liable to be overrun by the rank growth of bacteria.

Prevention of Posterior Bowing in Compound Fracture of Femur.—Alexander has devised a splint suitable for all fractures in the lower two thirds of the femur. In effect it is a double Thomas bed knee splint, an outer and an inner. The outer is the ordinary Thomas splint, and to its end the extension is fixed in the usual way. At the junction of the ring with the inner bar, and at the same level on the outer bar, is a pivot, to which is attached another—the inner Thomas splint (minus its ring): it fits easily within the outer, and is bent 4 inches from its lower end, so as to raise the whole off the bed. By raising the outer splint by its end the patient's thigh and leg are also raised, but the inner splint turning on the pivots remains resting on the bed.

Diagnosis and Treatment of Syphilis. H. C. Donald.—p. 65.
Self-Revelation. J. I. Robertson.—p. 73.
*Influence of Cerebral Symptoms on Prognosis in Pneumonia in Childhood. M. Putnam.—p. 84.

Influence of Cerebral Symptoms on Prognosis in Pneumonia.—The total number of cases of lobar and primary bronchopneumonia studied by Putnam was 120, with a mortality of 26, or 21.6 per cent. Nineteen, or 16 per cent. of the children, presented early cerebral symptoms, with two deaths, giving a mortality rate of 10 per cent., and of these only five demonstrated tetany. Six patients suffered from late cerebral symptoms with four deaths, or a mortality rate of 66 per cent.; of these four fatal cases three had pneumococcal meningitis. It is thus seen, first, that late cerebral symptoms are of much more serious import than early cerebral symptoms; second, that the mortality rate in cases with early cerebral symptoms is decidedly lower than that in the disease in children generally; and, third, that tetany could only be cited as a cause of the early cerebral manifestations in slightly over 26 per cent.

Massive Collapse of Lung as Result of Gunshot Wounds; Wounds of Chest. J. R. Bradford.—p. 127.

Spleen and Leukocytes in Trench Fever.—A palpable spleen was detected by Tate and MacLeod in 15 per cent. of the cases of trench fever observed by them. Total and differential leukocyte counts were made by the authors in twenty-seven cases of trench fever. Twenty-four counts were made on patients during pyrexia, and the average total count was 10,766. Eleven counts were made in apyrexia, giving an average total of 10,283 leukocytes.

Pathogenesis of Diphtheritic Paralysis Following Skin and Wound Infections.—Examination made by Walshe of a series of cases of diphtheritic paralysis following faucial and extrafaucial (wound and cutaneous) infections showed that palatal paralysis does not occur, except after faucial diphtheria. In extrafaucial diphtheria the paralysis often shows (27 per cent.) an onset anatomically related to the infective focus. Polyneuritis follows both faucial and extrafaucial diphtheria equally, and, irrespective of the site of the infective focus, presents a remarkably constant symptom complex. Paralysis of accommodation also follows both forms of infection, though the faucial more frequently (86 per cent.) than the extrafaucial (33 per cent.). It is, therefore, not a "local" paralysis, and its more constant association with faucial infections may be explained by the close proximity of the local central nervous system lesion in this case to the oculomotor nuclei. The palatal paralysis constitutes the "local," the ocular affection the "specific," and the polyneuritis the "generalized" forms of diphtheritic paralysis. In extrafaucial diphtheria, as in tetanus, the "local" paralysis varies with the site of the infective focus.

As for the pathologic processes underlying this symptom-complex, it seems highly probable that the local paralysis is an "ascending lymphogenous toxi-infection" (by the perineural lymphatics) of the central nervous system from the infective focus. The essential pathologic lesion here is central and not peripheral, and is situated in the nuclear complex already described. The ocular and generalized symptoms are probably the result of the circulation of the toxin in the blood stream, whence it gains access to the whole nervous system, central and peripheral. The essential nervous lesion here is probably both central and peripheral.

Respiration and Oxyhemoglobin Dissociation Curves.—The pulmonary ventilation, alveolar CO_2, alveolar ventilation, tidal air, dead space, and respiratory exchange were measured by Debenham and Poulton in ten normal men at rest in bed. The methods described by Haldane and Priestly, and by Hasselbalch and Lindhard, for measuring the alveolar CO_2 have been compared, and show satisfactory agreement. Values for K (the constant of the oxyhemoglobin dissociation curve) at the alveolar CO_2 pressure have been determined in eleven normal men, and agree with values previously published. Results for the buffer value of normal blood are given. The buffer value of blood in states of acidosis is considered.

Increased Acetone Production in Vomiting in Pregnancy.—Three cases are recorded by Gilliatt and Kennaway in which the examination of urine was found to be of some empirical value. It is noteworthy that two of the patients were Jewesses, and the only fatal case of vomiting of pregnancy in the records of the Middlesex Hospital for the last ten years was a Jewess. There was a history of the occurrence of vomiting in previous pregnancies in each patient. The authors point out that in some forms of pernicious vomiting a stage is reached when the ammonia index shows a rapid increase in the course of a few days to values between 30 and 50; at this time the acetone bodies are being produced in large amounts. The changes observed seem too great and sudden to be the result of starvation alone. When this condition appears, abortion seems to be the only treatment which is of any avail, and rapid improvement is to be expected from it in the great majority of cases. Attention is drawn to the great scarcity in the literature of adequate analyses of the urine in this disease, especially in regard to the output of acetone bodies.

Acute Infective Polyneuritis.—It is held by Bradford and his associates that so-called acute febrile polyneuritis is a very definite entity, capable of being separated clinically from other diseases of the nervous system. It is a diffuse affection of the nervous system affecting the spinal cord, spinal ganglia, and peripheral nerves, with but a slight incidence on the cortex. The lesion is essentially one affecting the nerve elements, cells, and fibers. The malady can be transmitted experimentally from man to the monkey, and the characteristic lesions reproduced in the experimental animal. A living virus can be shown to be present, both in the human cases and in the inoculated monkeys. The clinical and pathologic features of the disease have been reproduced in monkeys by the subdural inoculation of the emulsion of human cord preserved from twenty-five days to seven months in glycerin, and also by direct inoculation from monkey to monkey of emulsion of the fresh cord or of cord preserved in glycerin and, moreover, by the inoculation of the pure culture. These facts, together with the apparently definite incubation period of from five to six weeks, lead the authors to the conclusion that this is a specific infective disease of a gradually ascending nature from the nerves to the entire nervous system. Pathologically, it appears to be distinguishable from acute anterior poliomyelitis, although closely allied to it, and suggesting that this term and those applied to other hitherto obscure diseases of the nervous system (Landry's paralysis, acute ascending paralysis, polioencephalitis, and yet others) may ultimately be found to cover or be overlapping designations for a group of closely allied and infective diseases of the central nervous system.

Radiography of Normal Spine in Different Positions. A. de Marneffe.—p. 541.

Necessity for Maintaining the Balance in the Circulation.—Derache and his co-workers had occasion to ligate an artery or vein or both in forty-eight among their 7,914 cases of war wounds of vessels in different Belgian hospitals. They refer only to cases of definite ligation when there is no other chance of arresting the tendency to secondary hemorrhage. They say that the ligature should always be supervised with extreme vigilance as infection is liable to intervene; the wound itself and the temperature curve must be carefully watched. It is advisable to bury both stumps of the artery in muscle tissue as an extra precautionary measure; adhesions may then form with solid cicatricial tissue, reenforcing the other measures. After ligation of an artery, the blood passes on its way through collateral branches and these pass the blood on into the vein and into the venous collaterals. The balance of the circulation, the balance between the arterial and venous flow, is thus upset, and nothing happens to remedy it as there is no stimulus for formation of new venous collaterals. Therefore they advise as an indispensable complement of ligation of an artery that the vein should be ligated at the same time. By this means, as the arterial collaterals develop and enlarge from the extra functioning, the venous collaterals develop and enlarge to correspond, and the balance in the circulation is maintained. Whatever the injury of the blood vessels, when ligation is required, the vein must be ligated along with the artery. The obstacle to the passage of the venous blood favors the nourishment of the region, as the blood is kept longer in contact with it, and the tension of the blood is increased. The passage of the blood is thus in accordance with the normal balance between the arteries and the veins, and the arterial blood is not drained away too rapidly by aspiration into the main vein.

Sequels of Abdominal Wounds.—Stassen emphasizes that even after a man wounded in the abdomen has weathered the cape of the evacuation hospital and is apparently entirely cured, yet he is by no means out of danger. It is only exceptionally that full physical capacity is regained. His observation of five war *laparotomisés* with an interval since of three years, seventeen with two years and eight for more than one year has demonstrated that eventration, visceroptosis, disturbance from adhesions and the flaring up of a latent chronic peritonitis lie in wait for these men, and it is rarely that they escape one or more of these. In 10 per cent. an emergency laparotomy has been required since, and nearly 33 per cent. have eventration. Four cases showing the different types of secondary disturbances are related, and the degree of incapacity for each type is evaluated. Among his thirty cases, twenty had to be trained in a new trade or business, one that would make less physical demands on the abdominal wall than the man's former occupation. The new trades were in leather working, mechanical drawing, printing, electricity and wireless telegraphy, furrier, tailor or domestic servant.

Tube Casts.—Denoncin and Gillet affirm that tube casts are usually of greater import for diagnosis and prognosis than the albumin in the urine. They may occur before any albumin appears, and they may outlast the albuminuria. Tube casts, especially epithelial casts, are a more constant sign than albumin of injury of the kidney in the course of infectious disease or chronic interstitial nephritis. The quantity of the casts is also an index of the severity of the disease or toxic action affecting the kidneys. They insist that the tube casts should be investigated as well as the albumin in the urine before attempting treatment with arsphenamin or vaccines.

Traumatic Cataract.—Rasquin remarks that traumatic cataract in soldiers has often become spontaneously corrected, but when resorption is not complete he advises intervention. The evaluation from an industrial standpoint is the same as for aphakia. In any event, the evaluation done soon after the accident requires correction by a reexamination later.

Rheumatism.—Poynton declares that the study of heart disease should begin with the study of the infectious disease in childhood responsible for the heart lesions, before cicatricial changes have become definitely established. We cannot cure them when once developed, but cannot we do more to prevent their developing? He has been able to induce in animals, with streptodiplococci isolated from cases of acute articular rheumatism, not only multiple arthritis but pericarditis and endocarditis, not once but many times and with different species of animals. With acute rheumatism in children, the character of the food does not seem to have much influence; cold and dampness do not induce the disease but may predispose to it, and may render its course chronic and incurable.

*Caries of Upper Incisors. L. Dubreuil-Chambardel.—p. 84.
General Procain Anesthesia by Intraspinal Injection. Riche.—p. 86.

False Diphtheria Bacilli.—Martin and Loiseau acknowledge that when there are false membranes in the throat it is of little import whether the bacilli are of the true or false diphtheria bacilli type. But when it is a question of carriers, then it is extremely important to distinguish between the dangerous and the harmless bacilli. The false diphtheria bacilli do not kill guinea-pigs, do not produce toxins, and do not induce production of an antiserum. They grow only on the surface of the culture medium, and they do not turn it red as does the true diphtheria bacillus when the medium is tinted blue with litmus. Martin and Loiseau use test tubes 6 cm. deep, partly filling them with a 30 per thousand gelose. Then 3 gm. of glucose is dissolved in 200 c.c. of distilled water and 30 c.c. of tincture of litmus is added. The gelose is liquefied by boiling, then cooled to 50 C., and 5 c.c. of the litmus-glucose solution, after filtering through a candle, is added to the test tube and agitated till well mixed, after heating to about 50 C. The tubes thus prepared are tested for their sterility by keeping at 37 C. for twenty-four hours. The tube is then heated in the water bath and cooled to 50 C. and then inoculated with the broth emulsion of the bacilli to be tested, taken from a well isolated serum colony. By the eighteenth hour the tubes with true diphtheria bacilli have turned red, and colones can be seen throughout the depths of the tube, nothing on the surface. With the pseudodiphtheria bacilli, there are numerous colonies on or close to the surface, none in the depths, and the tint persists blue.

Herxheimer Reaction from Quinin in Malaria.—Autric relates two cases of malaria dragging along for several months in which the severe daily febrile attacks stopped immediately when all quinin was suspended. In one case the attacks did not return at all; in the other not until after five days. He explains such phenomena as a kind of Herxheimer reaction, and warns to be on the lookout for it. He is the médecin principal of the navy, and his experience at Madagascar and elsewhere has convinced him that the graver the form of malaria, the more cautious we must be in administering quinin.

Fly Killers.—Boyé and Guyot describe extensive research on ways and means to abate the fly nuisance. The practical conclusions are that castor oil and arsenic are the best fly killers. Castor oil containing a little sugar attracts the flies, and they die in and around it. Its action is enhanced by adding 20 drops of croton oil to 30 gm. of the castor oil. The fly dies almost instantly, while the oil is not dangerous for man. The odor of sugar and the odor of decomposing milk, flesh, or blood, seem to attract flies most powerfully.

Caries of Upper Incisors.—Chambardel calls attention to a form of caries which seems to attack simultaneously the four incisors in the upper jaw. He has encountered forty cases, all beginning at about the age of 14. There seems to be some anatomic deficiency in the bone rendering this group of teeth less resistant.

*Prevalence of Rabies in France. H. Martel.—p. 108.
*Public Health During German Occupation. A. Calmette.—p. 120.
*Bone Grafts. P. Mauclaire.—p. 126.

Operations on Children.—Kirmisson emphasizes the different character of surgery on children during the different periods of childhood, that is, under 5, between 5 and 13, and from 13 to 15. His statements are the results of his experience as the incumbent of the chair of children's surgery, founded for him in 1901. Among the points to which he calls special attention is the predominance of invagination of the bowel in infants, usually breast fed and well nourished. This should be suspected whenever in the midst of good general health an infant presents signs of occlusion of the bowel with bloody mucus in the stools. Strangulated hernia is rare in children over 5 but he has had 118 cases in children younger than this; nearly 50 per cent. were in infants less than a year old, including several less than a month old. The strangulation is unmistakably due to spasm, as also the invagination of the bowel in nurslings.

Another special feature of surgery on children is the predominance of fractures of the legs, instead of fractures of the arms, in younger children. In infants learning to walk the femur fractures with remarkable ease. Evidently muscular contraction is a factor, as the fracture occurs almost always in the middle portion of the bone, where the drag of the muscles tends to exaggerate the normal curve of the femur. Although the knee did not suffer from the traumatism, an effusion develops in it—an important aid in the diagnosis of fracture of the femur in an infant. In six recent years he had seventy-six cases of fracture of the femur in children under 5, and nineteen in children above this age, with sixty fractures of the femur and 108 of the arm in children over 5.

This same predominance of the femur in children under 5 is equally noticeable with osteomyelitis. The femur was affected five times more often than the tibia in children under 5 (twenty-one to four), while in older children the tibia was involved in forty-three and the femur in only thirty-two. In infants, the soft parts of the thigh are so thick in comparison to the bone that osteomyelitis of the femur is revealed only by a little swelling and may long escape detection. In older children the staphylococcus is generally responsible for the osteomyelitis, while in infants the streptococcus is more often to be incriminated, especially in the large abscesses in the shoulders and thighs of infants. In the thigh they may entail dislocation and this may suggest a congenital luxation when seen later unless the discovery of some small scar on the thigh or gluteal region gives the clue to the diagnosis.

Surgical tuberculosis in infants is generally superficial, restricted to the skin, as if the tubercle bacilli had been sown over the surface of the body. Hence result the glandular lesions in the neck, the diffuse lesions of the bones of the face and skull, and the multiple and symmetrical lesions of the small long bones of the hand and foot. It is in infants, moreover, that we more often meet with tuberculous lesions of the testicle. French clinicians seem to be unanimous on this point, and Kirmisson's experience has confirmed it. Malignant tumors in children over 5 are of the osteosarcoma type as a rule. But it is in infants that we find cancer of the eye, glioma of the retina, and cancer of the testicle or kidney. He warns that hematuria very seldom occurs with cancer of the kidney. The latter may be developing for a long time before any functional disturbance calls attention to it.

The surgical affections of children from 13 to 15 are mainly those affecting the locomotor apparatus, scoliosis, genu valgum, valgus flat foot and coxa vara. These may be encountered also in children under 5 but they have special characteristics in adolescents. The pain and contractures with valgus flat foot—*tarsalgie des adolescents*—do not seem to be ever encountered in children under 5. When a child of 4 or 5 has valgus flat foot, with more or less contracture, it will almost invariably be found to be the manifestation of a tuberculous process in the tarsus. A special feature of these bone deformities in adolescents is the great contrast between the poor and the well-to-do. Among the latter, tarsalgia is extremely rare while it is extremely common among lads just taking up work in trades, obliged to stand many hours at their work, possibly strained besides by carrying loads. They had no symptoms of the kind while they were at school; the tarsalgia first appeared after 13, when the boys left school and went to work. Kirmisson concludes by urging that school attendance should be compulsory till the age of 14, and that the working day should not be over eight hours.

Rabies in Dogs in France.—Martel relates that the strict measures against rabies in Paris resulted in a drop from 846 cases in 1901 to three in 1913. The abandonment of their dogs by refugees and the absence of veterinarians, drawn into the war, have resulted in a recrudescence of rabies. In 1918 there were 411 rabid dogs killed in Paris, and there were four cases of rabies in man, and 350 persons taking the course of treatment at the Pasteur Institute at Paris. The ordinances in regard to keeping dogs muzzled and on a leash are not heeded now by the public, and in 1918 throughout France 1,602 persons were bitten by rabid dogs, cats, cattle or sheep, with seven deaths, while 3,142 cases of rabies in dogs were reported.

Stunting of the Growth of the Young at Lille During the German Occupation.—See Paris Letter, page 742.

Bone Grafts.—Mauclaire has been much gratified at the successful outcome in seven of twenty-three cases in which he implanted a long segment taken from the fibula or other bone to bridge a gap in a long bone. He cuts the ends of the graft pointed and works them into the marrow cavity of the stump above and below. There must be an interval of several months before the grafting operation is attempted after the healing of the wound. If there was suppuration, six months at least must be allowed for the focus to become aseptic. He has compiled 128 grafting operations for war wounds. In nearly every instance an autograft was used, and seventy-two are reported as successful. It is evident, however, that a certain number of unsuccessful cases have not been published. In his own twenty-three cases, conditions were unfavorable in some, the skin very thin, and cicatricial tissue in the depths of the wound not offering very favorable chances for success. Sometimes an Italian grafting operation might prove useful to supply healthy skin under which to place the bone graft. He adds that Ollier's method of bone-periosteum grafts are of easier application. This technic was applied by the Japanese during their war with Russia in 1908. In the present war, Delagenière and Dujarrier have reported a number of successful cases with it. In one case Mauclaire surrounded the segment graft with a flap of bone-periosteum graft, thus combining the two methods. He gives an illustration of one case kept under roentgen supervision for two years. The bone segment did not become devitalized; it is living, and it has become very much hypertrophied. The graft was implanted to repair a loss of substance in the tibia; it has kept its shape and has not become porous. In another case the graft implanted in the radius became atrophied and deformed by the end of the second year. Probably the nourishment of the bone was defective.

Case of Abscess in Lung. Creyx.—p. 3.
*Spinal Anesthesia. H. L. Rocher.—p. 5.
*Osteosynthesis. Charbonnel.—p. 8.
*Training Troops to Walk in Water. P. Nadal.—p. 14.

Spinal Anesthesia.—Rocher has applied this method of anesthesia in 250 cases of war wounds and extols its advantages when lesions in the air passages render inhalation anesthesia inadvisable. It is ideal when, for other reasons, the patient is compelled to lie prone, and when extreme relaxation of muscles is desirable. It has been his experience that it reduces the shock with long or difficult operations, but in four cases he witnessed severe nervous shock come on from five to fifteen minutes after the anesthesia, but these men had grave septicemia or gas gangrene. This renders this technic dubious when the infection or intoxication is exceptionally severe. He reviews his experiences and the technic in detail, including eighty-seven peace time operations and 163 after war wounds.

Osteosynthesis.—Charbonnel comments on the increasing vogue of osteosynthesis as the danger of opening up a closed fracture does not exist with war wounds, as they are all compound fractures. The aim is to reconstruct the bone out of the fragments, fitting them into place as perfectly as possible and binding the whole into a sheaf by tying a wire around them. This prevents fragments of bone being pulled out of place by contraction of muscles. Fourteen cases of primary osteosynthesis are described to show its advantages, and he discusses further the field of early secondary osteosynthesis and of the same done tardily for old fractures, defective consolidation, and pseudarthrosis with or without suppuration.

Walking in Water.—Nadal urges training soldiers to walk through a running stream and walk entirely submerged for certain stretches. With a little training, he says, troops can thus accomplish the crossing of a river over 90 feet wide and not much over 9 feet deep, each carrying a load weighing from 66 to 88 pounds.

*Nephritis with Inherited Syphilis. V. Hutinel.—p. 65.
Trench Fever. Baudouin.—p. 73.
Autochthonus Balantidian Dysentery. Weil and Bergouiguan.—p. 76.

Nephritis with Inherited Syphilis.—Hutinel warns that mercury does not seem advisable in treatment of the nephritis with inherited syphilis. He has even witnessed hematuria follow mercuric inunctions, and consequently he refrains from mercury in treatment of nephritis with suspected inherited syphilis. Intravenous injection of an arsphenamin preparation is now his procedure. The diuresis increases and the general condition improves, but we must not expect rapid improvement or a definite cure. These can be counted on only when treatment is begun in the early stage, while generally the nephritis is far advanced and cicatricial tissue has formed at some points. However, the nature of the syphilitic affection in these cases, restricted to circumscribed regions, allows better hopes of a cure than with ordinary nephritis. In any event, the kidneys should be spared as much as possible. The inconsiderate use of excessive quantities of salt and nitrogenous foods is liable to bring exacerbations. This was evidently responsible for the successive outbreaks of symptoms in some of the cases he describes. The nephritis was of an acute type in several, including an infant of 19 months and boy of over 4. Examples of the chronic form are also described in a boy and girl of 11 and 13, and a man of 50. In some other cases in this group the chronic nephritis first became manifest after purpura or mumps or infection with tuberculosis. The nephritis does not assume any special type; in fact, the condition is not so much nephritis as it is that the renal reactions are modified by the specific infection. The kidney symptoms develop after such slight causes that we hesitate to incriminate them, a little redness in the throat, an intestinal affection or mild purpura or influenza. The fact that the kidney develops symptoms testifies to a special lack of resisting power. The albuminuria is usually out of all proportion to the functional disturbances; there is little tendency to edema and the blood plasma is nearly normal. Hematuria is not so frequent as in tuberculosis, but the tendency to relapse is the same, and hemoglobinuria is not rare. The nephritis passes into a chronic phase by successive *poussées*. Uremic manifestations are rare and tardy. Treatment of an underlying inherited syphilis may have a very favorable action on kidney disorders in children in particular.

*Trigeminal Paralysis. L. Testut and L. Marchand.—p. 37.
*Military Service After Wounds of Brain. Laignel-Lavastine.—p. 38.
Voltaic Vertigo with Skull Wounds. R. Dubois and A. Hanns.—p. 40.
*Precision with Wassermann Reaction. Mathis and Labougle.—p. 41.
*Prolonged Use of Heart Tonics. G. Galli.—p. 43.

Trigeminal Paralysis.—In Testut and Marchand's case the paralysis involved both the sensory and the motor trigeminal fibers. It was a sequel of cerebrospinal meningitis. The young man first noticed that something was wrong when he found that he was cutting himself constantly when he shaved the right side of his face. The progressive paralysis of the muscles of mastication and the anesthesia reached their height in eleven months, and then slowly improved to some extent. He also has attacks of pain at times, spreading to the back of the neck and the occipital region.

After Wounds of the Brain.—Laignel-Lavastine discusses different types of what may be encountered in men who have been wounded in the brain. He emphasizes the imperative necessity for placing such men in the hands of skilled experts with authority to keep the case for the treatment deemed desirable, and to determine his return to military service or not, unhampered by red tape. The pure psychoneuroses do not entitle to a discharge from the army.

The Wassermann Reaction.—Mathis and Labougle have slightly modified the technic advocated by Calmette and Massol, as they describe in detail. They laud it as a reliable, easy and precision method. With this more accurate technic, they found the response constantly negative with malaria, leprosy and Vincent's ulceromembranous stomatitis.

Prolonged Use of Heart Tonics.—Galli remarks parenthetically that we are accustomed to take 10 or 15 cg. of caffein in our cup of coffee every day. He does not know of any one who has taken up to 700 gm. of a 10 per cent. solution of tincture of strophanthus in the course of two years except the man of 50 whose case is described. He had mitral insufficiency and hypertrophy of the heart, well compensated, and had been taking 20 drops of the tincture daily for two years, on a physician's prescription. The latter had told him he would have to keep up heart tonics all his life.

*Vaccination against the Streptococcus. C. Levaditi.—p. 49.
Retrograde Peristalsis in Colon. P. Lignac.—p. 52.

Vaccination Against the Streptococcus.—Levaditi reviews the experiences with treatment of war wounds with a sensitized autogenous vaccine and also with lipovaccines and ether-sensitized vaccines. The work was done at the Virval Belgian ambulance, in charge of Professor Depage. Six tables are given to show the results in different classes of wounds, and with these different types of vaccines. The efficacy of the vaccine is shown most conclusively, perhaps, by the fact that in wounds of soft parts known to be infected with streptococci and requiring further operative measures, after the vaccine had been given, the wound healed smoothly without infection in 95.5 per cent. of the cases. This success surpasses the 93.5 per cent. successful cases among those known to be free from streptococci. With the vaccine to supplement the other measures, results as satisfactory are obtained with streptococci infection as without it except that healing takes longer. Generally, from twenty to sixty days in the graver cases are required before the wound can be definitely sutured. The dose of vaccine is 0.5 or 1 c.c. injected into the deltoid muscle and repeated every five or six days or alternate sides. The twenty-four hours broth culture of hemolytic streptococci is centrifuged and the sediment, in suspension in 10 c.c. of isotonic salt solution, is mixed with 4 c.c. of a mixture of ether and chloroform in equal parts. After twelve hours the ether-chloroform is decanted, and the suspension of the microbes is mixed with 4 c.c. of antistreptococcus serum. After four hours of contact at 38 C. the whole is centrifuged and the sediment is suspended in 10 c.c. of saline. After testing for sterility, it is injectable in the dose of 0.5 or 1 c.c. The intradermal test proved very instructive, the reaction being found most pronounced in the cases tending to healing, testifying to a vigorous defence on the part of the organism. In the cases of grave septicemic infection there was little or no local response to the intradermal test, hence the response to the test is a useful guide as to when the wound can be safely sutured.

*The Lumbago Question. D. Pometta.—p. 129.
Changes in Hair and Nails after Influenza. L. Merian.—p. 139.
Household Surgery in Switzerland. G. A. Wehrli.—p. 144.

Lumbago.—Pometta is chief of the Swiss accident insurance infirmary, and he here discusses some cases of lumbago in which there was a possibility of a traumatic origin. He regards lumbago as of rheumatic nature in the majority of cases, and even those in which a traumatic factor is concerned, are usually "traumatic" only in the medical sense and not from the insurance standpoint. The lumbago, however, usually comes on in a way which convinces the subject that it is of traumatic origin, but the activation of muscles and joints by early resumption of work is of great benefit unless the roentgen rays show actual injury of the bone. There are no objective findings with lumbago as a rule. Hematoma and swelling in the depths of the tissues generally escape detection; when such are found, they indicate a superficial and hence a milder lesion.

Present Status of Intestinal Sutures. E. Aievoli.—p. 32.
After the Victory. A. Ferrannini.—p. 37.
Protection of Motherhood and of Children. G. Tropeano.—p. 38.

Gangrene in the Gassed.—Silvan recapitulates the disturbances in the cardiovascular apparatus that have followed gassing with yperitis, the mustard gas. They include hematuria, gastrorrhagia, cyanosis of the extremities and purpura from the penetration of the toxic gases into the organism. In a case described, ischemic gangrene of the right arm compelled amputation, but the lungs were too badly damaged for recuperation, and the robust man died three weeks after he had been gassed.

Hematomas in the Ears of the Insane.—Romano has compiled seventeen articles dealing with what he calls otohematomas and their frequency in the insane. In a case described, periauricular blood cysts developed, apparently vicariously for an otohematoma, in an insane soldier of 34. These otohematomas are found in the insane with nervous disturbances, vasomotor or bulbar phenomena. They are a sign that recovery is doubtful and recurrence probable as they indicate an unstable vasomotor system.

Radiotherapy for the Eyes. N. Scalinci.—p. 92.
*Epidemic Encephalitis. G. Molinari.—p. 93.
Shape and Statics of Stomach. E. Aievoli.—p. 94.

Malaria, Quinin and Influenza.—Roccavilla regards it as significant that only twelve cases of influenza developed among 1,500 malarial patients deeply under the influence of quinin. The disease was exceptionally mild in those affected. He accepts this as testifying to a more or less protective action from the quinin. After the disease is once under way, quinin does not seem to modify it.

Eye and Skin Symptoms in Nervous Disease.—Gavazzeni and Jona noticed in certain cases a monocular divergent strabismus, most pronounced in the spontaneous movements of rotation of the eyeball. Either eye may be affected, and the intensity of the deviation always corresponded to the gravity of the cases in their experience. This symptom was present in 20 per cent. of their cases of nervous disorders bordering on psychoses or with cyclic recurrence. It is important both for diagnosis and prognosis. They also noted in many cases of minor nervous disturbances with a constitutional base, that the abdomen showed a number of spots like freckles, but the surface was slightly verrucous. They were generally grouped in the lowest intercostal space, with some scattered toward the stomach and umbilicus region. They accompanied the neuroses and subsided with them to a certain extent. The writers venture the suggestion that the suprarenals may be responsible for this skin symptom. The persons affected were usually hyposthenic and inclined to lassitude, and the spots became more pronounced during periods of depression.

Epidemic Encephalitis.—Molinari presents the actual status of this subject as it has been studied in France, Uruguay and Great Britain. No definite conclusions are possible as yet.

*The Food in Austria during the War: Effects of the Restricted Diet. L. Castaldi.—p. 601. Commenced in No. 49, p. 577.

The War Diet in Austria.—Castaldi was long a prisoner of war in Austria, and he made a special study not only of the food of the war prisoners but of the Austrian army and of the civilian population in the different regions he was able to investigate. He found in his own person that the organism adapts itself remarkably to an unaccustomed diet. While at one prison camp, the food averaged only 1,300 calories, as he describes in detail, and he suffered from anemia and reduced capacity for both physical and mental work; his memory in particular became impaired. But when he was transferred to Bistritz he received a total of 1,800 or 1,900 calories daily, and he soon recuperated and reached a stable balance, so that he felt physically normal. With 2,000 calories or a little less, the men in the prison camps kept up vigorous exercise, tennis, football and other sports in the best of health, demonstrating that this ration is sufficient for the ordinary occupations of civilians. Below 1,700 calories, the ration is absolutely insufficient, and the food supplied by the Austrians to their Italian prisoners of war was far below this figure for most of the time.

*Bronchopulmonary Spirochetosis. R. E. Ribeyro.—p. 351.
Case of Hodgkin's Disease. E. Odriozola.—p. 355.
*Trachoma in Peru. B. Burga.—p. 360.
*Influenza in Rio de Janeiro. E. Escomel.—p. 367.

Bronchopulmonary Spirochetosis.—Ribeyro publishes the second case of this disease kn[illegible] Peru. Th[illegible]tient was a Japanese of 30 who had [illegible] ing at I[illegible] eight years. The p[illegible]e diag[illegible] been p[illegible] tuberculosis, but the microscope showed the sputum swarming with spirochetes and no tubercle bacilli. Fever, cough and bloody sputum developed suddenly but the storm blew over in about a month. By the end of the month only a very few spirochetes could be detected, and there was scarcely any expectoration, the general health becoming satisfactory.

Trachoma in Peru.—Burga's figures give the number of cases of trachoma at the eye infirmary at Lima during the last nine years as ranging from five in 1910 to fourteen in 1916. Almost all the cases are imported. In the four cases during 1914 there was inherited or acquired syphilis in two. tuberculosis in a third, and the fourth man was a miner.

Influenza in Rio de Janeiro.—Escomel was on a visit to Rio when influenza broke out there, the first cases being ascribed to infection from the same steamship from Spain which passed on to Buenos Aires where also the epidemic followed in its wake. Within five days half a million of the people in Rio were affected, and all business and traffic were paralyzed. As the usual supplies from the provinces were thus cut off, there were no meat, milk, eggs or poultry to feed the sick. The schools were turned into hospitals, most of the drug stores closed for lack of drugs and clerks, and the government opened stations for free aid. The convicts in the prisons had to be called on to dig the graves as corpses were brought in such numbers. On one day there were 1,000 deaths. The physicians did heroic work; twenty-seven died within ten days. Of the 200 physicians who gathered at the opening meeting of the Medical Congress to which Escomel had come as a delegate, only thirty-two were present at the closing meeting, the others being sick, but there were no fatalities among the foreign delegates, but unfortunately the same cannot be said of the Brazilian contingent. The offers of the foreign delegates to assist in the hospitals were declined by the authorities. The epidemic seemed to be more deadly the nearer to the equator, growing milder farther south. Even at its height, there were never more than 200 or 300 deaths in one day at Montevideo or Buenos Aires. The epidemic was also milder on the Pacific Coast. In Peru, although there were 5,000 cases at Arequipa, yet few were fatal. Escomel adds that the disease seemed exceptionally virulent at Rio, as was evident by the way it attacked the foreign delegates and the 650 sailors of the U. S. cruiser *Pittsburg* in the harbor, 117 of whom died, according to press reports.

Hemianopsia; Three Cases. E. F. Sanz.—p. 1.
*Prolapse of Rectum in Children. A. Sierra.—p. 3.
Case of Choledochotomy plus Cholecystectomy. C. Roe.—p. 3.

Prolapse of Rectum in Children.—Sierra expatiates on the evils of attempting surgical measures of any kind for prolapse of the rectum in children. It occurs only from straining, from diarrhea, from helminths and from disease in the large intestine, and only in children debilitated or naturally delicate. Removal of these causes corrects the tendency to prolapse. In one case recently the prolapse persisted under all treatment until santonin was given. After expulsion of a number of helminths, conditions in the rectum returned to clinically normal. Electricity and local injections of strychnin or ergot are not of much use, but the child should be trained to defecate in a way to reduce the strain on the rectum, lying on the side, if necessary for this.

*Reconstruction of Angular Fractures. Villa-Zeballos.—p. 33.

Reconstruction of Fractured Bone.—Zeballos has been highly gratified by the way fractured bones with overlapping and diverging ends and fragments heal under the technic he describes with illustrations. It reduces the traumatism of the bone and periosteum to the minimum, while insuring the best possible conditions for repair. He ascribes the method to Gentil of Orleans. A metal bridge spanning the area of the fracture carries a small frame in which fits a long perpendicular screw. The frame bridges the area of the fracture and the screw is turned until it fits against the overlapping stump and pushes it down into place with gentle force. A bronze wire passed around the sagging stump and tied over the metal bridge lifts up this stump into place. Force can thus be applied in two directions from the horizontal bridge, and the force can be graduated to fit the changing conditions each day. The bridge permits lengthwise traction at the same time.

Revista de Psyquiatria, Lima, Peru

Hypochondria in Eighteenth Century. Moreyra and Paz-Soldan.—p. 1.
*Mutism. L. D. Espejo.—p. 11.
*Infantilism. H. Valdizan.—p. 25.
New Phase of Psychology. H. F. Delgado.—p. 37.

Mutism.—Espejo describes among others three cases of familial deafmutism in the children of a syphilitic and alcoholic father and epileptic mother. He is inclined to incriminate the syphilis in these cases. The children spoke normally for their age until *chupos* are said to have developed on the head, probably, he says, external manifestations of inherited syphilis or possibly only boils. This occurred at the age of about 18 months in each child, and thereafter the children grew deaf and forgot all the little speech they had learned. Another little girl of 4 after an attack of malaria lost vision, hearing and the power of speech for a few days. Then vision returned, then hearing, and speech last, but with stammering and defective enunciation, and the child presents some tics. The mother was of a nervous temperament and had once had an attack of mutism lasting for three days. In the other cases of hysteric mutism described, the patients were young women and a woman of 52. One, notwithstanding complete mutism at other times, talked freely in her sleep. The complete recovery under hypnosis and suggestion reaffirmed the hysteric nature of the disturbances.

Infantilism.—Valdizan's five cases confirm the share of the endocrine system in the morbid tendency which is manifested by infantilism. All were young men except one man of 56. In most of them the phase of infantilism followed some severe sickness, and under tonics and organotherapy clinically normal conditions were restored in time. Two were brothers, and albuminuria was among the first symptoms. He accepts it as an indication of the onset of the pluriglandular disorder, initiated in the kidneys and spleen. This assumption is confirmed by the retrogression of this infantilism under a course of tonics.

*Education of Epileptics. E. P. Rodriguez.—p. 56.
*Chicha, an Alcoholic Peruvian Beverage. H Valdizan.—p. 62.
Extrapsychiatric Psychanalysis. H. F. Delgado.—p. 78.

The Origin of the Amueshas.—Tello relates a myth from the folk-lore of the Indians of Peru.

Training of an Epileptic.—Rodriguez had charge of the education of an epileptic boy of 10 and he describes how with medical supervision it has proved possible to improve conditions immeasurably for the child. The disturbance in speech and the tendency to left paralysis suggest organic brain disease.

Peruvian Alcoholic Beverage.—Valdizan was surprised to find that among the inmates of the general insane asylum only fourteen or fifteen had a history of excessive use of chicha, the national spirituous beverage, and in very few was the chicha alone responsible. This rarity of toxic mental disorders from abuse of chicha can be explained, he says, only by assuming that chicha is harmless as some maintain, or that it acts in a different way from the habitual agents of alcoholic toxiphrenias.

*Surgical Treatment of Gastric and Duodenal Ulcer. R. Finochietto and R. F. Vaccarezza.—p. 699.
*Severe Hemorrhage from Graafian Follicle. D. A. Rojas and V. Widakowich.—p. 717.
Social Darwinism and Eugenics. R. Kehl.—p. 721.

Gastric and Duodenal Ulcer.—Finochietto and Vaccarezza analyze their experiences with seventy-five operative cases of ulcer in the stomach or duodenum. They give the details of a number of typical cases and expatiate on the importance of combining both medical and surgical measures; these do not conflict with but supplement each other. In hospital practice they operate in every case of chronic ulcer of stomach or the duodenum unless they are convinced that syphilis is a factor. In this case they give a course of specific treatment and if the results are not satisfactory, they operate, regardless of the syphilis although continuing treatment. In private practice they impose a rigorous medical course of treatment, not insisting on surgical measures until these fail. Gastroenterostomy is the operation of choice. With hematemesis they refrain from operating until a quiet interval. With subacute perforation, seen in the first twelve hours, they operate at once, but if over twenty-four hours have elapsed and the reaction of the wall is slight and the general symptoms mild, they order absolute local and general repose and defer the gastro-enterostomy until later. With acute perforation the operation must follow at once.

Hemorrhage from Rupture of Graafian Follicle.—Rojas and Widakowich retrospectively explain the case reported as a rupture of a congested follicle, a very rare occurrence. Neither in the ovary or tube were there any traces of an ovum. No large vessel was found open but a liter of blood was removed from the peritoneal cavity.

Notes on Influenza. R. Cabrera and A. Segers.—p. 733.
*Sugar Treatment in Tuberculosis. J. S. Picado.—p. 741.
Nervous Complications of Influenza. Goñalons and Carulla.—p. 743.

Intravenous Injection in Roentgen Diagnosis.—Greco suggests the possibility of obtaining instructive information by injecting some opaque substance directly into the vein of the region. This method seems logical and practical as intravenous injection of metal salts is practiced by many now in treatment of various processes. He does not know that this method has been applied in the living to date, but his experience with rabbits seems to show its feasibility. In his experiences in vitro the salts of mercury cast the best shadows, but quinin hydrochlorid in a 0.10 per cent. solution was nearly as effectual and tartar emetic—which is used so extensively now by the vein—casts as clear shadows as the mercury salts. The dose of the quinin would correspond to a dose of 0.09 to 0.12 gm. for a person weighing 60 kg. Introduction of coloring substances seems to be especially promising as they diffuse throughout the entire body.

Sugar Treatment of Tuberculosis.—Picado gives a tabulation of the results in nine cases of pulmonary tuberculosis given systematic treatment by injection of sugar according to the Lo Monaco method. The results were disappointing, no benefit being apparent except that in a few the cough and expectoration diminished. In others, benefit and aggravation seemed to alternate; in one the sputum showed blood for the first time, and in another the blood stained sputum seemed unmodified. The blood serum showed no increase in the sugar content. The great advantage of this treatment is that the cough and expectoration may be reduced without injuring the stomach.

Syphilis and Salvarsan. E. M. Villapadierna.—p. 1033.
*Etiology of Cirrhosis of Liver. L. Urrutia.—p. 1035.

Etiology of Cirrhosis of the Liver.—Urrutia in looking over the records of sixty cases of cirrhosis in adults found abuse of alcohol in 35 per cent., but in thirty-nine alcohol could not possibly be incriminated. In 15 per cent. there was a history of chronic malaria. In four of the women no cause for the cirrhosis could be detected. In 5 per cent. of the total, syphilis may have contributed although one of the twelve in this group was a habitual drinker. Banti's cirrhosis seems to be anatomically identical with Laennec's cirrhosis; of the seven cases of this kind, none had a history of abuse of alcohol. Consequently it is incorrect to call Laennec's cirrhosis alcoholic cirrhosis.

*Neurasthenia versus Uremia. C. Juarros.—p. 1053.
Congenital Gynatresia. J. E. Pallares.—p. 1054.
Differential Diagnosis of Appendicitis. T. Hernando y Ortega.—p. 1056. Commenced in No. 3390, p. 979.

Neurasthenia in Azouria.—Juarros applies the term *azouria* to a set of symptoms resembling diabetes insipidus but with abnormally large urea content of the urine and nervous disturbances. He reports in detail a case in a man of 48, a great smoker, with insomnia, loss of weight and nervous poise after a great grief. The symptoms suggested intense neurasthenia but examination of the urine showed oxaluria, indicanuria and 32.40 gm. urea to the liter. The absence of polyuria and of sugar in the urine excluded diabetes, and Juarros made the man stay in bed, on a milk vegetable diet, with lactic ferments and nerve tonics, brain organotherapy alternating with injectable nucleins and lecithin. Under this treatment the urea increased to 43.72 gm. per liter but the other symptoms showed improvement, and the urea also subsided to normal figures during the following month or so. After a period of comparative health the symptoms returned with the urea up to 37.80 gm. per liter.

Aphasia with Acute Febrile Process. E. F. Sanz.—p. 4.
*Treatment of Prolapse of Rectum. A. Morales—p. 7.
*Vacuum Extraction of Cataract. V. Moerno.—p. 8.
Leg Ulcers. Sicilia.—p. 9.

Prolapse of the Rectum.—In Morales' case the extensive prolapse kept recurring in spite of various palliative operations. The woman had had [illegible] erous growt [illegible] in

1916 from the rectum. He conquered finally the tendency to prolapse by inducing cicatricial retraction as after a burn. After a purge, he had the woman keep on her feet for a time to obtain the maximum of the prolapse. Then he anesthetized the whole of the prolapsed mucosa with an 8 per cent. solution of procain, after which he applied the actual cautery, burning parallel stripes with it, from above downward, the stripes close together. After waiting a few minutes, the prolapse was reduced, handling it with gauze, and the patient kept quiet in bed for two days. This procedure was repeated three times, at intervals of six weeks. The outcome was a complete success, the patient now being in apparent good health, free from both cancer and prolapse.

Vacuum Extraction of Cataract.—Moerno relates that Barraquer of Barcelona now has a record of 630 cases of cataract which he has removed in the capsule by his method of vacuum aspiration. He does from fifteen to twenty operations of the kind each week. Simple extraction was done in 391 cases, the combined extraction in 289; with a conjunctival flap in 436 and with a suture in 194. Vision was left from 0.7 to 1 in 398; from 0.3 to 0.6 in 185; from 0.1 to 0.3 in 44, and 0 in 8. In the total 630 cases, 34 complications were encountered, hernia of the vitreous in 5; inversion of the flap in 2; rupture of the capsule in 3; luxation of the lens in 2; infection in 2; hernia of the iris in 5; hemorrhage in the anterior chamber in 3; impaction of the zonula in 4; iritis in 1, and hyphemia in 7. He calls the method facoerisis. It was described in The Journal, Dec. 8, 1917, p. 2006.

Treatment of Influenza. J. G. Castro.—p. 25.
Dermatologic Centers in New York. J. L. Carrera.—p. 28.
Inspiration and Therapeutics. B. H. Briz.—p. 29.

Subsidence of *Rhinophyma* Under *Radium*.—Ratera has been unable to find more than seven cases on record of radium treatment of rhinophyma, but his success in the case reported justifies its wider use. The radium was applied for twelve hours on four successive nights, by Degrais' technic, filtering through 2 mm. of lead the rays from 16.4 mg. of radium sulphate on a circular plate, 25 cm. in diameter. Three exposures were made forty days later, and two more after an interval of two months, to remove the last trace of discoloration.

***Morbid* Constitutions.**—The main points of Calleja's article were summarized in these columns, March 15, p. 837.

Hospitalstidende, Copenhagen

Dec. 11, 1918, **61**, No. 50

*Atypical Forms of Meningitis. F. Rydgaard.—p. 1713. Conc'n.

Atypical Forms of Meningitis.—Among the cases reported by Rydgaard are two in which an aseptic purulent meningitis in a boy of 3 and man of 28 was accompanied by diphtheria bacilli in the throat. It is possible that the toxic meningitis in the course of diphtheria may be comparatively frequent but escape recognition. He knows of only a few cases on record, including Reiche's three cases. Glaser has contended that diphtheria meningitis may develop with scarcely any manifestations of the diphtheria in the throat. Rydgaard's two patients were treated with an antimeningococcus serum, and recovery promptly ensued, but prompt recovery is the rule in this type of aseptic meningitis. In a third case of aseptic purulent meningitis the young woman had developed infectious sore throat but diphtheria bacilli were not involved, and the meningitis here also was evidently of purely toxic origin. The bibliography appended shows that an aseptic purulent meningitis may develop in the course of uremia or parotitis, or with lead or ptomain poisoning, after spinal cocain or stovain anesthesia, with infectious processes in the vicinity of the meninges, and with abscesses at the back of the neck. One case is on record in which a nonsyphilitic woman for several years developed aseptic meningitis every month in connection with menstruation. There is also a series of cases on record in which absolutely no cause for the aseptic meningitis was detected.

*Bacteriology of Lupus. A. L. Fønss.—p. 1745. Concluded in No. 52, p. 1777.
Present Status of Döhle's "Inclusions" in Scarlet Fever. F. Thorborg. —p. 1762.

Bacteriology of Lupus.—Fønss' report covers 25 cases of lupus, 3 of verrucous tuberculosis and one each of dubious diagnosis and scrofuloderma, a total of 29 cases. The tuberculin skin tests elicited reactions of the human type in 22; 11 gave the strongest response to bovine tuberculin and 9 to human tuberculin; in 2 cases the response was alike for both. He tabulates 103 cases from the literature in which bacteriologic investigation showed the human type in 81 and the bovine in 18. In Denmark about 14 per cent. are bovine cases to 86 per cent. human. The German figures are 12 and 88 per cent. and the English 48 and 52 per cent., respectively, while no bovine cases seem to have been published in Italy and France. In Fønss' three cases of typical bovine tubercle bacilli, the lupus was of a severe type but the progress of the lesions was arrested by Finsen light treatment and they healed over. In these and 14 similar bovine cases from the literature, the lungs, epididymis, glands and bones showed other manifestations of tuberculosis in 8 of the total 17. This also occurred in 12 of a total of 30 cases of the human tubercle bacilli type, typical in 10, with attenuated virulence in 17, and atypical in 3. In 11 cases of verrucous tuberculosis, the patients were all butchers, and in all the lesions were of bovine origin. In the other 4 cases there was no known contact with cattle and the affection was of the human type. The clinical course of lupus does not seem to depend on either type exclusively, mild cases and severe and extensive cases occurring with each. Simultaneous skin tests with both bovine and human tuberculin are unable to differentiate the infection from them. The literature on the bacteriology of tuberculous skin lesions is reviewed and the clinical details of the total 29 cases are given in full.

*Effluence from the Human Body. S. Alrutz.—p. 1393.

Effluence or Radiation from the Human Organism.—Sydney Alrutz is lecturer on psychology at the University of Upsala, and for years he has been compiling data for a large work on the dynamics of the nervous system, conducting experiments on the suggestibility, the motility, sensation and nervous energy in the waking and the hypnotic state. He here devotes sixty pages to the illustrated description of experiments which he asserts have apparently demonstrated the existence of a hitherto unknown radiation, effluence or emanation from the human organism which affects the sensation and muscular contraction in the human body exposed to it. His research was done on two persons who were readily hypnotized for the experiments, and also on a number of normal persons. There seems to be an emanation of some nervous influence from the finger tips as they are passed without contact over the body of the subject. This influence was evident in changes in the sensation and muscular contraction of the part of the body forming the field of the experiment, anesthesia, analgesia and muscular contraction being observed. This effluence seems to pass undiminished through a sheet of glass or metal but seemed to be arrested by cardboard and wool. The illustrations show the blindfolded, hypnotized patient as subjected to the various tests, the arm in a large glass box, for instance, or the effluence transmitted through a glass rod without actual contact. Alrutz found that the effluence can be reflected against a sheet of metal, and also be conducted through a rod bent at a right angle or twisted. Even pointing the finger, above the sheet of glass, toward a muscle or tendon was followed by the contraction of the muscle or tendon. He emphasizes the similarity of the phenomena thus induced and some of the phenomena of hysteria. The discovery of this emanation of nervous energy tends to throw light on the phenomena of hypnotism as the hypnotizer makes passes without direct contact.

GENITAL DEFECTS AND VENEREAL DISEASES AMONG THE PORTO RICAN DRAFT TROOPS

HERMAN GOODMAN, B.S., M.D. (NEW YORK)
First Lieutenant, M. C., U. S. Army; Officer in Charge, Venereal Infirmary
CAMP LAS CASAS, PORTO RICO

The calling to the colors of 12,000 men between the ages of 21 and 31, nearly all natives of Porto Rico, gave an opportunity to study the genital defects and venereal diseases, including syphilis, prevalent in one of the West Indian islands where syphilis is supposed to have had an early start.

Especial interest should be manifested in the report of syphilis among the troops, as evidenced clinically, and by the Wassermann reaction taken as a routine on bakers and cooks. The Wassermann reports were in accord with the clinical findings in every case of secondary syphilis, and in cases of primary syphilis in which the draining lymph nodes were enlarged. In the latent tertiary cases, negative Wassermann reports were returned in only six cases that treatment with mercuric salicylate in grain doses weekly for six weeks provoked a positive reaction. It might be well to note that in every case the only information the laboratory had was our serial number. We believe, from correlating the clinical findings with the laboratory reports, that the latter are trustworthy as indicating syphilitic infection, and do not hesitate to base conclusions on them.

PORTO RICO

In the report of his observations on the skin diseases of Porto Rico, King[1] gave a brief description of the climate and people of Porto Rico, because few persons have any adequate idea of the place, and it would afford readers a better appreciation of the diseases under discussion. King, who is a trained observer and has spent many years on the island, said:

> Porto Rico, lying on the eighteenth degree of latitude, comes within the geographic boundaries of the "tropics," and the prevalent American idea, fed by popular fiction, pictures the West Indies with a hazy mixture of extreme heat, palm trees, and scantily clad "natives," with dread diseases of all kinds lurking in all corners.
>
> In Porto Rico palm trees are plentiful, to be sure, but the climate, while warm, is tempered by sea breezes along the coast and by the altitude in the interior. It is seldom sultry, even in the hottest months, and the summer averages cooler and more pleasant than in the United States. There being but comparatively slight difference between summer and winter, the climate is monotonous, and the uninterrupted warmth probably has important etiologic influences acting directly or indirectly through its effect on the susceptibility of the person, on the organisms which cause disease, or on the agencies which may transport disease.
>
> The people of Porto Rico are descended from two principal sources: the European settlers, chiefly Spanish, and the slaves imported from Africa, the aboriginal element having been so nearly exterminated in the early days of colonization that it may practically be ignored. A fairly numerous foreign contingent is composed of Europeans and Americans, and a recent immigration of a few thousand negroes from other West Indian islands. We have, therefore, in Porto Rico a mixed population, the white race greatly predominating, the black race in much smaller number, and a large element of the mixture of the two races in varying proportion. The habits of the people and the conditions under which they live and work are those of the tropics rather than those of the temperate zones, and apparently most tropical diseases, including those of the skin, should find suitable conditions for development. At the same time, the island is not so far removed geographically, climatically or in other respects from temperate climes but that the diseases of those regions might also find conditions more or less suitable to them.

GENITAL DEFECTS

The present study was made from the adult men of such a population. The scrunity of admitting officers and the inspections after assignment to companies tended to put into the hands of the venereal officer a larger number of suspects than would ordinarily volunteer for consultation. It is not surprising, therefore, that almost 10 per cent. of the men of the command have been observed by this officer in the three months that the men have been in camp; 1,163 patients have been registered at the venereal infirmary.

Hydrocele is one of the most common genital defects found. It is almost an insular characteristic. The cause is variously given, but the prevalence of filariae is generally thought to be the etiologic factor. Fifty-two men came to the infirmary with hydroceles of various sizes. In not a few, it is no exaggeration to say that the scrotum hung as low as the knees. Strange to say, a hydrocele of more than moderate size, and usually bilateral, gives the Porto Rican no apparent discomfort. For many years the trousers made on the island allowed for the extra mass. Many men wear suspensories, as might readily be supposed, but more for appearance than for comfort.

Elephantiasis of the scrotum accompanies few of the cases of hydrocele. The *Filaria sanguinis-hominis* is the etiologic factor here as in hydrocele. Of course in men already passed as fit for military service by local boards, we did not see the enormous masses that once were scrota, and which old textbooks usually represent as being carried about in a wheelbarrow.

---

[1] King, W. W.: Some Observations on the Skin Diseases of Porto Rico, J. Cutan. Dis. 35: 459 (Aug.) 1917.

Varicocele has not been of common occurrence. In only two cases was this noted to be at all large, and in one of these there was an accompanying completely descended scrotal hernia.

Cryptorchism, or undescended testicle, was found in only one man. There was no palpable mass either along the canal or in the left half of the scrotum. There was no scar of operation or injury, and the man stated that he had never had more than one testicle. We classified this case as abdominal retention of testicle, left side. The man was, of course, accepted for service.

Phimosis was a common condition. In many cases the opening was extremely small and the flow of urine impeded. The preputial cavity became an accessory bladder, so to speak, from which the urine slowly found its way to the outer world.

Seven cases of cicatricial phimosis were recorded. Wassermann tests were always taken on these patients, but the results were negative.

One patient with gonorrheal urethritis had an exceptionally tight prepuce as a therapeutic obstacle.

Balanoposthitis is a common condition in phimotic cases; but we have noted, in addition, the almost universal disregard for cleanliness under the foreskin even when it can readily be withdrawn. The skin of the glans and the mucous surface of the prepuce become soggy, moist, eroded, and even ulcerated. We considered the possibility of the erosive chancre in these cases, have searched for *Spirochaeta pallida*, and have taken Wassermann tests repeatedly in these patients.

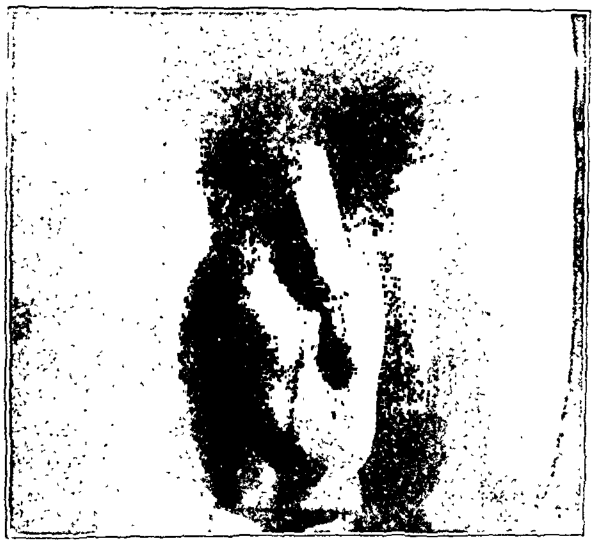

Fig. 1.—Hydrocele and elephantiasis of scrotum.

Paraphimosis we have recorded twice. Once it was a complication of acute gonorrheal urethritis.

Redundant prepuce is a relative term, to be sure, but all our men would be benefited by circumcision. In every individual examined, the entire glans was covered completely, and usually there was an inch to spare.

Operation was advised only in those cases of extreme phimosis in which it was not possible to expose the meatus urinarius. These men, we thought, were not safe for field duty.

One case of congenital stricture of the meatus urinarius was observed. Unfortunately for this man, the stricture was large enough to admit the diplococcus, although the tip of the urethral syringe was too large.

Urethral stricture was encountered only in those cases in which there were symptoms. In two of these the stricture had tightened down so as to admit only a filiform bougie. We are told that the urethra of the Porto Rican is almost as subject to excessive scar formation as that of the negro, and that stricture is locally regarded as part of the course of urethritis. We have not been able to confirm this statement.

Tinea cruris, or the eczema marginatum of the older writers, was encountered in only three cases. King thought that this is "a very common disease in Porto Rico and is seen with remarkable frequency in persons of excellent sanitary habits." He recognized the unity of this infection with the interdigital eczema recently popularized as Ormsby's tinea. We have diagnosed tinea of the crural region, armpits and toes in the same case.

Sebaceous cysts of the scrotum are common among these people. Although we registered only three at the infirmary, we have seen scores at our inspections that were never examined at the infirmary. The tumors are always multiple, and we have counted as many as seventy of all sizes on one man.

Pediculosis pubis was found twenty-four times in one regiment within a few days; recognizing an impending epidemic, we took measures that limited the ravages of the pediculus.

FRAMBESIA, OR YAWS

We recognized two cases of frambesia, or yaws, among the enlisted men. Each already presented the generalized eruption of crusts under which were the strawberry pulpy masses. The *Treponema pertenue* of Castellani was demonstrated in the lesions from both patients, and the Wassermann test was + + + + in both men. One patient was treated with 0.3 gm. of arsphenamin at weekly intervals for two weeks, and the lesions entirely receded. King "did not see the disease in its active stages nor encounter *Treponema pertenue*, although it was sought in the skin lesions of suspicious nature or history."

Captain Gutierrez, M. C., U. S. Army, tells us that he has records of seven cases, in not all of which, as we supposed should be the case, was the Wassermann test positive. The presence of concomitant syphilis must always be considered, but yaws is known to be one of the diseases that gives a "paradoxical" positive Wassermann test in the absence of syphilis.

REPORT OF CASE

The patient treated for yaws at the camp was a private, aged 24, who had been in service two months. He presented about twenty-six lesions, which were crusted, umbilicated and dry. Under the crusts was a moist, papular pulp. *Treponema pertenue* was demonstrated in smears. The Wassermann test, Aug. 7, 1918, was + + +; August 21, + + + +; September 13, + + + +. August 22, 0.3 gm. of arsphenamin was administered; August 28, 0.3 gm., and September 16, 0.4 gm. September 3, 1 grain of mercuric salicylate was given. The delay in initiating treatment was incident to the transfer of the patient to the base hospital and his return to the camp.

URETHRITIS

We were careful to instruct all company commanders to get their men who had or had had venereal disease to volunteer for treatment. If on future examination, they were told, venereal disease was disclosed, they would be punished. In this way many chronic cases were disclosed in which treatment was required. In a few cases, syphilis or gonorrhea was acquired prior to entry into the service, but the incubation time was spent in the camp. One case that had graver consequences than most was that of an accepted candidate for the officers' training camp. On the night before the opening of the camp, he took his last "fling." He passed his initial examinations after entrance. About five days after, he noticed a serous discharge but laid it to the unaccustomed physical exertion. The primary stage of the urethritis passed into the purulent period and he was speedily taken from the ranks. The finding of the gonococcus of Neisser in smears shattered this man's hopes for a commission.

In a few cases, an unrecognized and not reported chronic urethritis developed acute exacerbation after varying periods of drill. These men were sent to the base hospital. If the man had had a pass since entry into service, it became a nice task to distinguish between a case of urethritis acquired prior to entry or since entry into the service, and hence General Order 45, 1914.

A number of men admitted to the army with venereal disease were immediately sent to the base hospital for treatment. Under the old laws of enlistment, these men would have been rejected; but the Selective Service Regulations wisely provided for unconditional acceptance in all cases of gonorrhea, acute and chronic, and of syphilis with remediable manifestations.

We hesitate to say that infection was acquired with intent to evade military service, but it is certain that at least 25 per cent. of these men acquired their infection between the time at which they learned they were going to camp and the time they actually arrived there. One thing that led to the belief that a venereal disease would disqualify for service was the fact that members of the officers' training camps were discharged from the camps if they developed gonorrhea or syphilis. In a circumscribed community as this island is, such discharges and the cause thereof speedily become public property among the registrants.

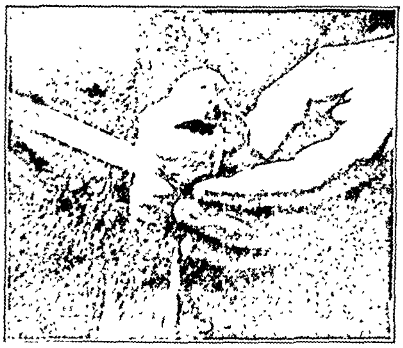

Fig. 2.—Chancre, ulcerative type.

One hundred and fifty-three cases of acute or subacute urethritis were registered. Of these men, ninety-eight with purulent, bacterial urethritis were sent to the hospital as incapacitated for field service. The subacute cases require a word further because in this island urethritis has an extended period of virulence. The reason is the universal practice of self treatment, for among all classes of society, the milk of the coconut is regarded as a specific for urethritis. "Coco de agua" is proclaimed by high and low alike, and it bears the recommendation of the very best medical authorities. The favorite prescription is a dram of Epsom salt placed into the opened nut and taken in the morning. The élite use a gram of sweet spirit of niter instead of the more proletarian Epsom salt. An average coconut contains 500 c.c. of fluid, so the therapy satisfies the thirst, irrigates from within, and the dram of magnesium sulphate has a physiologic effect on the bowels.

Of chronic cases of urethritis, we found 241 in camp. These men presented little or no discharge, had had urethritis, and the urine showed shreds, or was cloudy (not phosphates or carbonates). These men were found without treatment to develop an acute exacerbation following the drill and physical exercises of camp life.

These patients were treated daily except Tuesdays and Sundays. A card for each patient was kept with name, diagnosis and organization. The date and character of the treatment were entered on this card. When the urine became clear, this fact was noted. It was remembered that it takes at least 4 ounces of urine to wash the anterior urethra completely; also if the patient did not fill two glasses, it was not wise to give him credit for a clear urine because the patients soon learn to urinate a few moments before coming for the test, and the urine they do pass is clear. After a patient had five clear urines on five successive days or with a Sunday or Tuesday intervening, he was discharged from treatment, and allowed to have a pass. We were able to use in the treatment of these chronic urethritis cases potassium permanganate solutions varying from 1:1,000 to 1:3,000. In other cases we gave Ultzmann's solution of zinc sulphate, 2 gm.; lead acetate, 2 gm.; phenol, 2 gm., and water, sufficient to make 1,000 c.c.

All fluids injected into the urethra were a little above body heat. Glass urethral tips were sterilized by boiling each time used. In giving the irrigations for anterior urethritis, the irrigating can containing the fluid was not more than 2 feet above the level of the penis. The flow of fluid was interrupted so that it was not forced behind the constrictor muscle and so set up a posterior complication.

In only occasional cases did we find posterior urethral involvement. For these we gave retrojections of physiologic sodium chlorid solution, 2 per cent. boric acid solutions, or Ultzmann's solution in half or quarter strength.

SYPHILIS

The syphilitic lesions we have seen differ in no way from those seen in the United States. Of chancres, we have examined the small papular chancre; the papular necrosive chancre; the indurated ulcerative chancre (hunterian), and the erosive chancre. As often before demonstrated, the frenum is a point of lowered resistance to the entry of *Spirochaeta pallida*, and at least half our cases presented the initial lesion in this location. A fairly common type of initial lesion is presented by multiple lesions of the prepuce at its free border, a sort of rosette, accompanied by much edema. In one case a lesion within the preputial orifice gave rise to much suppuration. *Spirochaeta pallida* was demonstrated in this case, and arsphenamin therapy gave immediate results.

Patients were admitted to the service with the clinical diagnosis of primary syphilis who had passed the primary serologic stage and were in the "silent generalization stage" of syphilis: that is, presented chancre and no secondary lesions of skin or mucous membranes, but in whom the Wassermann test was reported + + + +.[2] We conceive of the local glands having been invaded by the syphilitic organism and from there having entered the general circulation through the medium of the major lymph channels. *Spirochaeta pallida* is free in the blood at this period, but no metastatic foci have had time to evidence themselves.

There were eighteen cases of recent secondary syphilis with generalized eruptions. The macular, the maculopapular, and papular ulcerative lesions of the secondary period were all seen. Flat condylomas, mucous patches, and the split papule of the corner of the mouth were observed. In one case the flat condylomas extended along the raphe of the scrotum, along the ventral surface of the penis, and in the penile scrotal sulcus.

---

[2] Goodman: Diagnosis and Treatment of Syphilis in Men, Am. J. Syphilis 2:344 (April) 1918.

We found on the examination of the blood in 262 cases presenting scars of penile lesions, of healed buboes, or of ulcers of the lower leg or about the knees, that 108 had a + + + + Wassermann reaction. These cases we considered in the latent tertiary stage or the stage of potentially active syphilis. They were all treated.

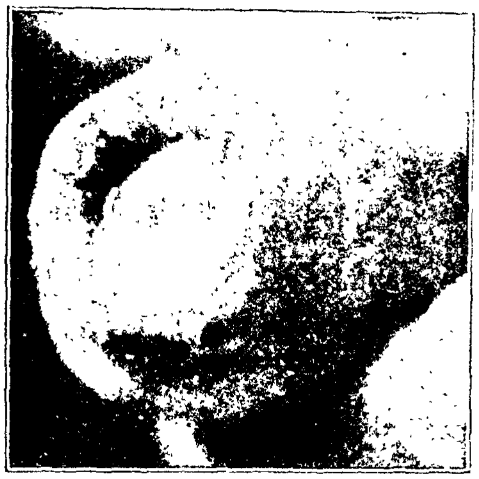

Fig. 3.—Multiple chancre; rosette of lesions.

Many men examined volunteered the information that certain scars about the lower legs (clinically not syphilitic at all) were the result of syphilitic infection. Blood tests in these cases were negative. In fifty such instances the men were given mercuric salicylate for six weeks in 1 grain doses each week, after which another Wassermann test was taken. The mercury did not provoke a single positive result. We are led to agree with King, that of the numerous skin ulcers coming under notice in Porto Rico, the vast majority have seemed to be due to ordinary pyogenic infections.

Active tertiary lesions of the gumma type we have not seen at all. In one case a patient presented serpiginous ulcerating lesions of both palms. The Wassermann test was + + + + and there was ready response to arsphenamin therapy.

We did not expect to find in a selected group of men between 21 and 31 years of age the disfiguring, large, ulcerating lesions of late syphilis with which this island is supposed to abound.

We recognized one case of hereditary syphilis by the saddle nose. There was no history of infection, and the Wassermann reaction was + + + +; but neither teeth, eyes nor ears gave any indication of the syndrome of late hereditary syphilis.

We thought it would be interesting to obtain a syphilitic index, so to speak, of the command. For this purpose we took the blood Wassermann test on all the bakers and cooks. This test served also to determine the fitness of these men for their special duties.

The first series consisted of ten civilian cooks, and four had + + + + Wassermann tests. One other cook had a + Wassermann and a history of syphilis. This series indicated that the infection index of syphilis would be 50 per cent. The next series was 151 enlisted cooks. Of these, twenty-eight, or 18 per cent., gave a total inhibition of complement, and five more gave a + +. Another series of twelve civilian cooks was next tested, and three were positive. The difference of infection can be thought to be due only to the difference in age groups of the civilian and enlisted men. The latter were all under 31 years of age. The bakery unit was formed in camp, and according to regulations, the blood test was done on all its members. Sixty examinations were made, of which fifteen, or 25 per cent., were + + +, or + + + +.

The total number of routine examinations of enlisted men was 211, with forty-three positive, or 20 per cent. The smaller series of civilians was twenty-two, of which six, or 27 per cent., were positive. In neither group do we consider in these summaries the inconclusive results of + or + + Wassermann reactions.

It is interesting to compare these figures with those of other sections of the United States. Pusey[3] says:

> The best estimates that we have in America come from some examinations of men in the public service. Reasoner, from a study of one regiment of the United States Army, estimated that 7 per cent. of the men were syphilitic. Bartlett, for another regiment, estimated that 10 per cent. were syphilitic.
>
> Vedder and Hough, from a valuable study of 1,283 cases in the government hospitals for men in the public service from all parts of the United States, estimate that 10 per cent. represents closely the prevalence of syphilis among men in the United States.
>
> Nichols of the United States Army, who has given great attention to the subject of syphilis in the army, believes that for the army as a whole the rate is something over 5 per cent. and, contrary to the common impression that syphilis has a high percentage in the army, he brings forward good reasons for believing that the prevalence of syphilis is not higher in the army than among men in general of the same age.

TREATMENT OF SYPHILIS

The cases we treat in camp are limited to the noninfectious cases by the orders of the Surgeon-General. This is as it should be, for, in the close association of camp life, it is best not to expose the healthy to the possibility of unmerited infection.

All patients with chancres and with the open lesions of syphilis are transferred to the base hospital. Opportunity for research of an advanced character is hardly given by a field service, but the safe and approved therapeutic procedures are all used. These are outlined in "The Manual of Treatment of the Venereal Diseases" and schematized in a circular of the War Department, Office of the Surgeon - General, Aug. 29, 1918.

In brief, they provide for the administration of arsphenamin (in our cases, arsenobenzol, Dermatological Research Laboratories) not oftener than once in five days, in dilution of 25 c.c. to the decigram, and in dosage of 0.1 gm. to each 30 pounds of body weight, for a course of six injections. Mercuric salicylate in 1 or 1½ grain doses intramuscularly once a week for nine weeks is given concomitantly with the arsphenamin injections. In our own series of cases, to the noninfectious Wassermann-positive, latent tertiary syphilitics we gave courses of mercuric salicylate injections of 1 grain doses for six weeks, rest for four

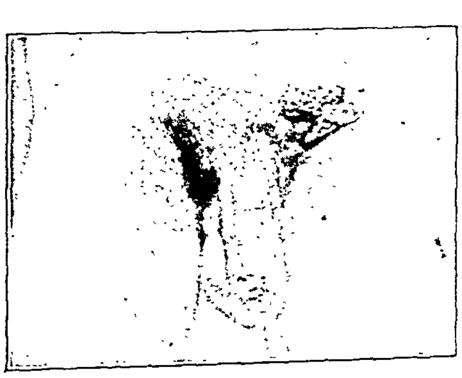

Fig. 4.—Condylomata lata in incision for syphilitic bubo.

3. Pusey, W. A.: Syphilis as a Modern Problem, Chicago, American Medical Association, 1915.

weeks and repetition of the mercury course. A blood Wassermann test was always done at the beginning and close of a course. Patients with recently acquired syphilis, on return from the base hospital, were given courses of arsphenamin. Other patients who had had infectious lesions of syphilis just prior to entering the service were treated with arsphenamin to prevent secondary or recurrent secondary lesions.

There should be no more difficulty in treating syphilis in the field than in any well regulated outpatient hospital service; in fact, it should be much less difficult because of the control of the men which the army affords. Intravenous therapy is feasible, and with proper preparations of the apparatus, freshly distilled and boiled water, patient without the previous meal, and with the bowels clear, there should be no reactions.[4]

MEASURES FOR THE PREVENTION OF VENEREAL DISEASES

After three months in camp, during which time the number of enlisted men rose from 250 to 12,000, only nine new cases of venereal disease were acquired. We are proud of this low number among a population so recently under military control. A high standard was set and no infections among soldiers was the aim. To this end, every measure advised by the Committee on Venereal Diseases in its "Program of Attack on the Venereal Diseases" was carried out. The campaign against incapacitating soldiers by avoidable diseases deserves a separate paper, but the broad outline may briefly be given here.

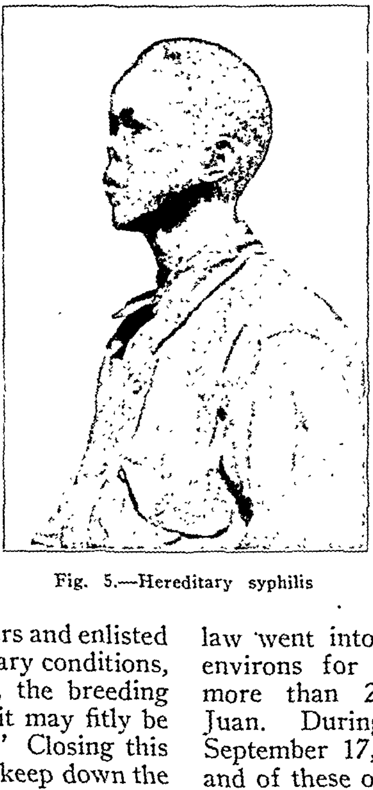

Fig. 5.—Hereditary syphilis

No passes for enlisted men were issued until the facilities at the venereal infirmary for prophylaxis had been established. The character of the order permitting passes was suggested by the venereal officer at the company commanders' meeting when the matter was brought up for discussion. Puerta de Tierra, in guide books called a suburb of San Juan, was declared out of bounds for both officers and enlisted men. The sanitary or rather lack of sanitary conditions, the prevalence of all sorts of diseases, the breeding place for every epidemic on the island, it may fitly be called "the place that God never knew." Closing this part of the island has certainly helped to keep down the venereal rate. Passes to San Juan and adjacent towns were limited to daylight except to married men whose families lived in these towns. Passes to more distant parts could be issued for over night. The number of men allowed passes was put at 25 per cent. of the command.

A personal inspection of cities and towns within sixty miles of the camp was made on the first Saturday and Sunday that the men were given freedom, and the conditions were found to be so bad that a campaign to exterminate prostitution was planned. As a forerunner of the power of the military authorities to close cities to men in uniform, Maniti was declared out of bounds to enlisted men. In this city more than seventy prostitutes were known to the police, and forty-eight were registered at the police office. In the streets on which these women lived, a policeman pointed out to the investigator eight houses with the assurance that he could find pleasure within.

The aid of the attorney general and the chief of the insular police was enlisted, and by a concentrated movement of both these officials, prostitutes who had formerly all been tolerated, even though known and registered at local police stations, were arrested and sentenced to six months or one year in jail. Heretofore, short sentences of fifteen days or fines had been imposed. This action on the part of the civilian officials took place one week after the pass order was given, so it will be seen that the possibility of infection was immediately reduced. It should be added that the first week of freedom immediately preceded a pay day, and the majority of the men were without funds. As the police cleaned up town after town, conditions about the island became much better. A uniform was avoided by the "ladies of light living," and the facilities for prophylaxis were not taken advantage of for good reasons.

Characteristic of all movements for the better, San Juan, the largest city of the island and nearest to the camp, was the most backward in this elimination of evil. The principal papers were actively antagonistic toward the efforts for cleanliness. Editorially and otherwise, adverse criticism was heaped on the crusade to prevent infection among present and future soldiers. The camp surgeon was instrumental in having the order prohibiting enlisted men going to San Juan except on official business. This order came out on the Friday preceding a pay day and a Labor Day holiday.

Here are a few figures to show the extent of the socal evil in San Juan: At the time that inspection and regulation were in vogue, more than 1,500 women were inscribed public prostitutes. At the time the "5 mile" law went into effect, some 600 left the city and its environs for other parts of the island. By June, more than 250 of these had returned to San Juan. During the entire campaign from July to September 17, only forty-two women were arrested, and of these only twenty-six were sentenced. During the two weeks that the city was closed to soldiers, forty-eight women were arrested by the federal authorities who, until that time, had taken no action under the federal law which had already been extended to include a 10 mile zone about cantonments and camps.

Preceding and during all this campaign, efforts to reach the public through the press were initiated. Many articles were published through the medium of the Police Women's Reserve Corps, formed under our immediate supervision. Much credit for awakening the local chapters of the American Red Cross, the Council of National Defense, the W. C. T. U., and the purely local societies, such as the Ministers' Union, to the pressing need, must be given to Mrs. Edith Hildreth, who publicly sponsored the "Clean up your town" campaign.

[4] Compare Goodman: Preparation of Solutions of Salvarsan and Arsenobenzol for Intravenous Use, New York M. J. **107:** 1122 (June 15) 1918.

Step 5.—The superficial tissues are closed by routine methods, and a small dry dressing is applied.

Step 6.—Care must be taken to provide suspension of the testicles in order to prevent the postoperative swelling and the subsequent induration of the scrotal end of the cord.

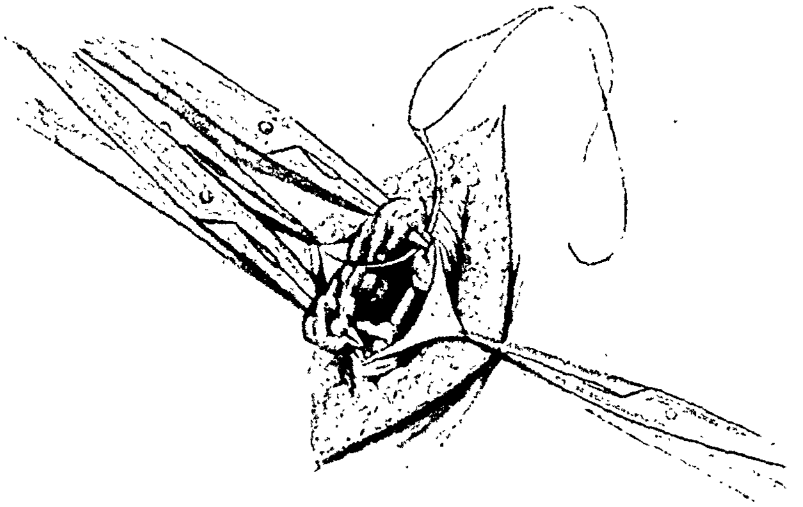

Fig. 4.—Raising up spermatic veins, disclosing vas lying in bottom of wound.

COMMENT

No priority is claimed for this method. An excellent description of a similar operation is found in Taylor's "Operative Surgery." Very few textbooks pay much attention to the cosmetics of varicocele or to the details of this simple operation.

There is no necessity for subjecting the vas and its accompanying vessels to trauma, yet most operative methods include as a step the lifting of the cord from its bed. This greatly increases the postoperative induration. Induration should be a rare sequela. In this method the tissues are subjected to a minimum of trauma. I have followed the principle of this method for a number of years in operating aboard ship for varicocele under local anesthesia without distress to the patient. Handling the vas is liable to be painful and makes complete anesthesia difficult.

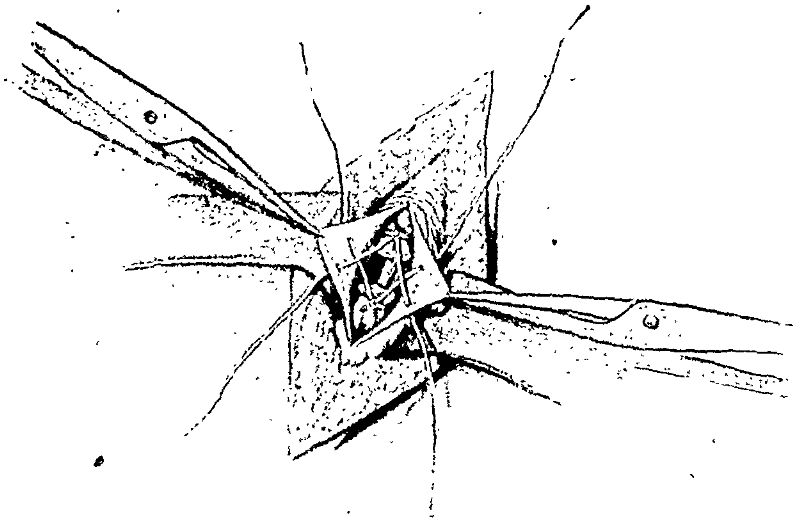

Fig. 5.—Manner of passing ligatures used to tie spermatic veins for closing cord covering.

The spermatic artery is excised with the spermatic veins, no attempt being made to separate it. Bevan[1] satisfied himself by a review of his own varicocele work, and by a review of experimental work on dogs to determine the blood supply of the tests, that there were two distinct and separate sources of blood supply for the testicles, namely, the spermatic vessels, and the other vessels accompanying the vas, either of which were quite sufficient to maintain the nutrition and the function of the organ.

I am indebted to G. V. Schwarz, the artist at Naval Hospital, Philadelphia, for the excellent illustrations of the operative steps.

U. S. Naval Hospital, Philadelphia.

HOSPITAL STANDARDIZATION

WITH ESPECIAL REFERENCE TO MEDICAL EDUCATIONAL WORK IN HOSPITALS *

A. R. WARNER, M.D.
President, American Hospital Association; Superintendent, Lakeside Hospital
CLEVELAND

There are few social institutions progressing and changing so rapidly as hospitals. At the present time, therefore, "standardization," in the sense in which that word is usually used, which would mean the determination and use of types of institutions and types of work generally accepted as best, is clearly impossible. Types would be out of date long before they could become established. On the other hand, progress and enthusiasm have made many dissatisfied with conditions which are as yet quite general, and which should unquestionably be replaced by better methods. To those who have thought most about the problem, "hospital standardization" includes the setting of minimum standards; but this only as a minor feature. The majors are the development of the institution to meet more effectively and more efficiently in every way occasions for work from the front door to the ash pile. In this sense the word "standardization" will hereinafter be used. The hospital is a more complex institution than is commonly understood by trustees, managers and department workers, including the medical staffs. In fact, it is often a question if they have not become too complex to be managed successfully by superintendents now available. It is unusual for men to develop real interest in so many and so different human activities as a modern hospital must include.

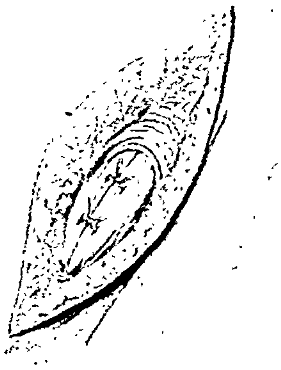

Fig. 6.—Closure of wound by tying of two sutures, as described in article by Dr. Angwin.

MULTIPLE FUNCTIONS OF HOSPITALS

It was not long ago that hospitals were merely institutions for the care of the ill, for the physicians. Then hospitals assumed the responsibility for educating and training professional nurses. We are more or less familiar with the expansion of hospitals as social institutions, not only in the development of the work generally called "social service" work, but also in the work of the institutions in the broad general development of sociological progress. The words "reconstruction work" have come to have concrete meaning. There is today the responsibility to utilize to advantage the convalescent patient's idle time, in educational, Americanization or occupational study. There exists a responsibility to the patient's home and family. The various sociological institutions of an organized community are now holding hospitals strictly responsible for a cooperation in work and for a consideration and service to patients other than medical. There has also come the demand on hospitals to train and develop various types of technical workers, so that many hospitals now have definite courses of instruction for this purpose. This list includes institutional dietitians, anesthetists, technical laboratory workers, nurse maids for children, and a few others. The dispensaries (or outpatient departments) of hospitals were called such because the first institutions dispensed drugs on prescription to the worthy poor. The present diagnostic treatment and educational functions of dispensaries are late developments. Until very recently, outpatient service was confined strictly to the same worthy poor. Of late, however, the evening pay clinics have been developed which extend this service, particularly in the specialties, to the working man of small income. The present policy of the government in regard to venereal disease will necessarily write a new chapter in the development of dispensary work.

---

[1] Bevan: Surgical Clinics, p. 1103 (Dec.) 1918.

* Read at the Fifteenth Annual Conference of the Council on Medical Education of the American Medical Association, Chicago, March 3, 1919.

The standardization of a hospital means the standardization, development and balancing of all these activities: one measure cannot be applied to all. Certain limited groups, as the American College of Surgeons, limited in the sense that their part in the work of a hospital is limited, have become deeply interested in the problem and have, I believe, quite unfortunately called this ambition and the efforts to better conditions "hospital standardization." There have been corresponding ambitions in various other groups of hospital workers, as the nurses, the dietitians and social service workers, as well as other groups in the medical profession. It is obvious that the work of these various groups, which have no contact or common ground outside of the institution, should somehow be correlated, harmonized and utilized to the advancement of hospitals and hospital work. Some disinterested and impartial agency or organized group of agencies should be developed to accomplish this task, and to round out hospitals to meet better the needs of the various communities. In doing this, it is likely that hospitals will be divided into various types to meet the various needs; and then, as these various types become clearly and generally recognized, the practitioner and the public will not be misled as to the kind of service a given institution can be expected to render. All this is a tremendous task. Who should do it? It has seemed to many an established principle that it would be unwise for any department to attempt to standardize the whole. There are some who would adhere to this principle so closely as to feel the impossibility of establishing a standardization in medical departments, pathologic departments or laboratory departments which was developed by, or generally believed to be developed through, representatives of the surgical department. The nursing departments, the social service departments and others would not for valid reasons readily accept the standardization worked out by a medical department, or all the medical departments combined. If the task were a matter of simple standardization in the ordinary meaning of the word, an independent foundation or commission might undertake it; but the problem is too great and too varied, the ideals too indefinite, and progress too rapid to permit this. The agitation of any group, however, for minimum standards, for classification of work and for development will easily accomplish results more than justifying the effort, especially if a way can be developed to put into operation with some expediency the unquestioned recommendations for good.

As long as the American Hospital Association was simply a voluntary association of hospital administrators, little could be accomplished through this organization. At present, however, the American Hospital Association is in the process of transition to an association of hospitals as the constituent members comparable in every way to the national associations of various trades and industries. As soon as this transition is completed, this association will have the attention of hospital trustees and managers who are keenly alive to the advantages of a national association in any industry, and there will be established an organization which can theoretically at least put into effect by the pressure of influence and public opinion, if not by law, various reforms leading to more rapid advancement in minimum standards. It is the opinion of some also that through this association there can be worked out a classification or typing of hospitals, so that the type and the work in a given institution is fixed by minimum standards and is known to all. It is principally in the interest of the public and humanity in general that these changes should be brought about, yet this in no way lessens the benefits to the medical profession, or to other groups of workers or to the institutions themselves.

All efforts toward hospital standardization have a positive and direct effect on medical education, which is the topic of especial interest to this meeting and which must be standardized with the rest of the institution.

A frank discussion of medical education, as carried on by the hospital, strictly from the standpoint of hospital aims and strictly in the interest of hospital development, may help in the determination of common ground and in the standardization of this work. This paper represents such a discussion, so far as I am entitled and competent to write it.

RESPONSIBILITIES OF HOSPITALS

The modern hospital has direct responsibilities in the education of undergraduate medical students. Here, and here only, is clinical material collected together and combined with facilities for this work. It is probable that only a comparatively few hospitals will ever be called on to provide facilities of this sort, and few hospitals other than university hospitals can be used to advantage in this work. It is, however, clearly the duty of the institution which can be helpful in this way to accept this duty and carry on such activity. These hospitals do now and will in the future more sharply comprise one definite type.

In the last few years there has been a tendency to reduce greatly the amount of didactic instruction in the fourth year and to assign these students to ward work in hospitals. At Lakeside such students are called clinical clerks. They do not lodge in the institution, but spend practically the entire day on the wards at this work. It is unquestionably more effective to teach clinical medicine at the bedside, and the fourth year students may well be taught largely by this method; yet in order to carry this out satisfactorily there is the necessity of a sufficient number of class hours, ward walks, etc., to make the experience to these students in work comparable to intern experience extremely limited. The visiting physician or surgeon does not find them at all times available. The tendency, therefore, is to organize and carry on the routine work without them. They remain students only. The greatest value of such a system has been its service in establishing its own defects. It has demonstrated, first, that fourth year medical students are not yet in a position to secure maximum advantages from internship work. It has demonstrated the value of and need for more bedside instruction in order to develop an advanced generation of physicians. It has brought out the need for a required fifth year to be spent by all students strictly as interns on a general rotating service. This will permit further development in the fourth year instruction along lines of clinical pathology, ward walks, etc. After the fifth year spent as intern in general or rotating work, the student is prepared to undertake special work. It is my opinion, based on observation of the results at Lakeside, that it is unfortunate for fourth year medical graduates to go directly into special services, even to services limited to general medicine or general surgery. There is apparently more loss than gain, and until the fifth year is established it seems better that internships should invariably be general or rotating. This program of a fifth year will bring distinct betterment in hospital work, and hospitals are therefore interested in its adoption.

On the other hand, graduate medical instruction in some forms and to certain degrees is possible in every hospital and should be carried on to the maximum extent. Every hospital has this opportunity, and its responsibilities to society are not properly discharged until it does its best, at least in the matter of advancing the professional attainments of its staff and such other physicians as work in the institution. It may be that a hospital may not feel that it owes anything to its staff or to the medical profession as a whole. It may feel that the financial advantages to the staff are greatly in excess of the return by the staff to the institution, and this may be true; but this in no way discharges the responsibility of the institution to the future sick and to society to advance the medical skill of these men as far as possible, and to do this without thought or consideration of the benefit to the physician personally.

Another obligation on hospitals is the training of postgraduate medical students in the form of interns or fifth year students. Like many hospital activities at the present time, the value, excellence and efficiency of this work now varies greatly. The real purpose and justification of this system (better care for the future sick) is not always the controlling factor it should be in the practical working out of the plans. Too often it is considered, on the one hand, as a system to get routine hospital work done cheaply and, on the other, a benefit to the individual intern. There is an immediate value in this system to the intern and to the hospital, but this alone does not justify internships, and the young graduate in medicine certainly does not owe this service to hospitals. The internship must justify itself as service to medical progress, to better public health, and must be judged solely by this standard. There is the obligation on the medical schools to assume some responsibility in guiding their graduates in the selection of internships to insure maximum development of these graduates.

NUMBER OF HOSPITALS AND GRADUATES

The number of hospitals is increasing rapidly. The number of medical graduates is for the time being decreasing. The trend is such as to make it improbable if ever again the medical schools will produce enough graduates in medicine to provide interns for all, or even a large proportion, of the hospitals of the country. The internship as an essential organization of hospitals is gone, and substitutes for this system must be produced. It is certain that as the disparagement between the number of hospitals and the number of medical graduates increases, the tendency will be for interns to seek the educational opportunities offered by the larger, better equipped and more active hospitals, and quite properly so. A salary connected with an internship will not make good deficiencies in educational opportunities. With this in mind, it has been suggested that there be developed a specially trained nurse who knows something of anesthetics and laboratory work to take over intern work in the smaller, so-called "nonteaching hospitals." Such an arrangement would facilitate the "standardization" of internships for the better, assist positively the demarcation of types of hospitals, and open a new field for nurses. To the patient in the small hospital without well organized visiting staffs, it is a question between the trained nurse responsible actually and directly to the attending physician, and the raw, untrained intern with a new license to practice and a feeling that his first allegiance is to his dignity. Experience would lead some of us to choose the nurse.

If the final decision is what now seems probable, i. e., that the first year after graduation be spent in a general or rotating clinical hospital service, the number of hospitals that can be developed to offer attractive and sound educational opportunities for this year will undoubtedly exceed the number of medical graduates. After this first year of general clinical work, there should exist in a certain number of hospitals opportunity for specialization and opportunities wherein a student may spend from one to five years additional in special training either in general surgery, general medicine, or in any of the specialties. Only a limited number of hospitals will be able to carry on work of this nature. This number will be greatly increased over the number now engaged in this work by the general and lay recognition of the simple and accepted principle that surgery or any other specialty can be developed to higher skill by several years' residence in a hospital offering adequate facilities than by the more usual method of working into the specialty from general practice. If this is recognized by hospital trustees, the assuming of the obligation to develop future specialists by this method is assured. In order to accomplish this it may be necessary that at least the latter years of this training be based on fellowships that provide living expense; but the education of the general public in the value of this work will promptly produce the necessary funds, as it is unquestionably a wise investment for the philanthropic.

THE BASIS FOR COMPENSATION OF THE SOLDIER FOR CARDIAC DISEASE *

J. C. GITTINGS, M.D. (PHILADELPHIA)
Lieutenant-Colonel, M. C., U. S. Army; Chief of Medical Service
AND
BERTNARD SMITH, M.D. (LOS ANGELES)
Captain, M. C., U. S. Army; Chief of Cardiovascular Division
LAKEWOOD, N. J.

Nine months of experience on the disability board of General Hospital No. 9, where we have had unusual clinical opportunities for the study of patients suffering from various forms of cardiac disorder, have enabled us to draw some practical conclusions which may be of use to demobilizing boards.

The determination of disability hinges on diagnosis, so we may consider, in some detail, the classification of cases as they appear for discharge.

Functional cardiac disorder may be considered first. In this nomenclature, we have followed the revised manual of the Medical Department in preference to the other terms which are coming into more or less general use, such as "effort syndrome," and "neurocirculatory asthenia." The classification adopted covers various types under this heading, cardiac disorder functional, namely, constitutional inferiority; defective physical development; neurotic type; postinfectious type; postrheumatic type.

In the diagnosis of cases of cardiac disease the history is of the utmost importance and must be elicited with special care to avoid "suggestion." This was obviously necessary in dealing with the recruit who was desirous of avoiding service. At present, the danger seems less, since exaggerated claims of disability which existed prior to military duty tend to minimize the responsibility of the government and lessen the chances for compensation. With care, however, it is usually possible to arrive at a fairly accurate estimate of the soldier's physical and mental type before enlistment.

1. CONSTITUTIONAL INFERIORITY WITH CARDIAC DISORDER FUNCTIONAL

This general term is used to cover all forms of inferiority except that of chronic invalidism, which is of sufficient frequency to be given a separate heading as defective physical development.

These individuals give a history of more or less disability from earliest childhood, in which various illnesses may have played a rôle, but in the main they are essentially and primarily lacking in ambition, courage, energy, aggressiveness and endurance. As boys, they never played games requiring physical stamina, both because of a lack of the normal spirit of contest or sport, and because participation produced the syndrome which stamps the disorder. Usually there is associated mental deficiency in the sense that these patients appeared to be incapable of advancing beyond the lower educational levels under ordinary stimuli, and as they grew older were content with a low economic level in the job that made the fewest psychic and physical demands compatible with their economic needs.

Physical examination of such patients is essentially negative. Physical development usually is somewhat below normal, and the muscle strength as shown by the Martin test may be below the standard; but more often the defect is not physical in a strict sense. Subjectively they complain on exertion of dyspnea; an early sense of general fatigue; cardiac palpitation; precordial pain, distress or tenderness, and vertigo, in the order of their frequency and importance. The area of cardiac dulness is not increased, tested by physical examination and by roentgen ray and the electrocardiograph. The pulse rate is unduly accelerated by any physical exertion and usually by excitement, although the time for the return to the normal rate for the individual may not be greatly prolonged.

The first sound at the apex as a rule is exaggerated and short, often suggesting the snapping first sound of mitral stenosis. At times a suggestion of a presystolic thrill can be felt in the erect position, and it is not hard to imagine that a faint presystolic murmur is heard. In the supine position the presystolic factors quickly disappear in contradistinction to the accentuation usually found in true mitral stenosis.

In this connection, it is interesting to note that the presystolic element in normal heart sounds, which Dr. Wiggers of Cornell University Medical College has demonstrated by the phonocardiograph, is a plausible explanation of the thrill and murmur. Whatever their origin, it is noteworthy that they are felt and heard almost invariably in the individual with the thin chest walls, which so greatly facilitate sound conduction. This type also exhibits with great frequency the basal systolic roughening or bruit, heard best in the second or third left interspace close to the sternum, and more pronounced in the supine position.

Regardless of the type of the chest, a soft systolic apical murmur is usually heard, loudest in the supine position and not transmitted, while cardiorespiratory murmurs are more or less common. The point of maximum intensity may be pronounced, and is often diffuse, depending both on the type of cardiac contractions and on the resiliency and thickness of the chest wall.

These "constitutional inferiors" are essentially useless for military purposes. Under ordinary conditions of recruiting the majority would be recognized and rejected by experienced army surgeons, not so much on account of the cardiac condition, but because of their evident inaptitude for service. Whatever the claims of these patients may be, it is a perfectly fair assumption that their condition has not been made materially worse by army service, because they have instinctively avoided severe exercise on account of its results. The soldier of this class who reports at sick call, or enters the hospital within one month or less of the time of his induction or enlistment, cannot be said to have suffered any real harm from his military efforts, and disability should be rated below one tenth to exclude the individual from compensation.

2. DEFECTIVE PHYSICAL DEVELOPMENT WITH CARDIAC DISORDER FUNCTIONAL

In these patients we have a physical defect more or less in evidence. Of most frequent occurrence is the so-called habitus enteropticus—the chest of the "carnivorous" type with relaxation of the abdominal muscles, while those of the chest and limbs are poorly developed. Usually the muscle strength test falls below the normal limits, and general nutrition is poor. The early history resembles that of the constitutionally

---

* From U. S. Army General Hospital No. 9.

inferior type so far as it concerns the ability to indulge in physical exercise, but there is not the same pronounced lack of ambition. Very often they have had serious and numerous illnesses during childhood, which may have been etiologic factors in the maldevelopment. This type must be carefully differentiated from that which suffers from the cardiac syndrome accompanying active tuberculosis. A comparatively small number of our patients exhibited definite, arrested tuberculous lesions. From the history it was clear that this had been the most important factor in the defective development.

The individual of the "defective physical development" type has often been encouraged or compelled by his physician or his parents to lead an inactive life because of an evident lack of physical stamina, or a belief that the heart was not "strong." For the same reason, as he gets older he selects the occupation that requires the least physical exertion, but his ambition and intelligence as a rule compel a higher economic return than that accepted by the constitutionally inferior type.

The actual cardiac findings on physical examination differ in no material degree from those found in Class 1. The subjective symptoms are the same, although the early sense of fatigue often plays a more prominent rôle than dyspnea.

The marked instances of this type likewise are essentially useless for military purposes and should never have been passed for military service. As a class, however, they go farther without a breakdown than do the constitutional inferiors, and in many instances are entitled to compensation because the breakdown occurs after several months of military duty, and in all probability results therefrom. Any other physical exertion, however, of the same degree would have produced the same result.

Most of the men belonging to these two groups are total abstainers from alcohol, not from any moral reason but because the effect is unpleasant. Tobacco and coffee apparently bear no essential relation to their symptoms. In the laboratory studies these patients show abnormal responses to sympathetic stimulation, and various degrees of disturbance in the glands of internal secretion. They stand at attention with muscles relaxed and the weight of the body resting on the pelvis. Their coordination is poor and they cannot be persuaded or forced to make the full effort at any time. Consequently they show very slight gains in strength, even after several months of daily exercises. Such men seek any excuse to avoid physical exertion and are often falsely accused of malingering. Careful electrocardiographic studies often show pronounced changes in the sympathetic control, such as could easily give rise to the disturbing symptoms. This causes one to doubt the wisdom of forcing men so generally below par to make their full effort unless they are under very close observation.

The following are given as sample histories of cases in these groups:

Case 1.—*Defective physical development.*—B., a soldier, aged 23, who had been in the service ten months and had performed no active duty, had had convulsions in infancy and had never been strong. His parents had been warned that he had a weak heart and that he must never be left alone. He had never walked over one mile a day. He had never taken any part in athletic games. He had had no serious illnesses. His parents were well. His mother was nervous. He had finished high school at 19. He had had no regular occupation. He always has had precordial pain, shortness of breath, and rapid, pounding pulse on slight exertion. He was easily fatigued. He had never fainted, but was dizzy on sudden change of position. The heart was normal in size. There was a soft systolic blow at the apex, standing, which disappeared on lying down and after exercise. Electrocardiograph showed a sinus arrhythmia; rate, standing, 112; lying, after fifteen minutes, 88; after exercising, 130. There was a slight tremor of the hands. The thyroid was palpable. There were no eye signs. The basal metabolism was normal. Strength : weight = 13.[1] After two months of daily exercises, strength : weight = 17.2. There was marked precordial tenderness.

Case 2.—*Constitutional inferiority.*—S., aged 25, who had been in the service four months and on active duty three days, was still in the fourth grade in school at 16. He never could take part in any games or do any hard work on account of precordial pain, dizziness and fatigue. He had frequently changed work because of symptoms. He had worked as a rag sorter before service, and had earned $10 a week. He had been satisfied and had liked the work because he could sit down and take his own time. His mother was nervous. His father was alcoholic. One brother was epileptic. The heart was normal in size. There were no murmurs. There was no tenderness. The thyroid was not palpable. There was marked tremor and a slight lid-lag. The basal metabolism was normal. He could not learn to execute the command: "About face." He showed marked difficulty in all the balancing exercises. He knew little about the war. He did not read the newspapers because reading made him nervous. When he entered, strength : weight = 16.8.[1] After six weeks of daily exercises, strength : weight = 17.7.

At times we find an individual whose cardiac disorder is out of all proportion to his physical defects and who is far above the constitutional inferior in intelligence and ambition. His former occupation, selected without regard to his health, made so few physical demands that he was totally unprepared for the severe strain of military training. Overzealous drill sergeants, or the hurried demands for even untrained men in France, forced this soldier at a pace beyond his limited endurance. His cardiovascular system apparently broke under the strain in spite of undoubted courage and a will to carry on. In this type can be accomplished the most striking cures, in a literal sense, from graduated exercises. Such patients should not be discharged until ample opportunity for cure has been afforded.

3. CARDIAC DISORDER FUNCTIONAL, NEUROTIC TYPE

In this we have the clinical picture of the neurotic or neurasthenic individual whose phobias have been directed to the heart. Ambition and intelligence are not lacking to the same extent as in Class 1. In place of these we find nervousness, unrest and hypersensitiveness, with the cardiac symptoms dominant. Palpitation, precordial pain and vertigo are more pronounced than actual fatigue, while the dyspnea is more subjective than objective. In the presence of slight enlargement of the thyroid, which sometimes occurs, differentiation of this type from that of true hyperthyroidism at times is difficult. In this connection it must be emphasized that slight enlargement of the thyroid, plus tremors of the hands and an easily excitable heart, do not constitute a syndrome on which to base a diagnosis of hyperthyroidism. The large majority of patients admitted to the hospital with this diagnosis have been found to have a normal basal metabolism. Hyperthyroidism to the extent of causing cardiac disturbance and nervous unrest, which at the same time fails to increase oxidation, is of a type that must be explained on purely hypothetic grounds.

---

[1] The strength was estimated by the Martin spring balance test. Strength to weight normal values were obtained on 100 soldiers who had had over a year of hard training. The average S/W value for these men was 24.5.

A careful history of these patients of the neurotic type shows that the cardiac disorder dates back to early childhood, while the thyroid enlargement in cases of true exophthalmic goiter can be proved clearly to have been of recent development. In a few of our patients the history pointed to a definite exophthalmic goiter, which developed since childhood and which had apparently left a residuum of thyroid enlargement and exophthalmos. In the presence of a normal basal metabolism it was necessary to interpret the cardiac symptoms either as a sequel of the active exophthalmic goiter, or as a concomitant defect of the nature of that which forms the basis for all of these functional cases.

Whatever the explanation, these patients of the neurotic type are not suffering from hypersecretion of the thyroid gland, so far as can be determined with present-day facilities. They deserve compensation only when their ambition has led them to disregard symptoms in the attempt to carry on, with consequent damage to structures — cardiovascular, nervous, or whatever they be — which are fundamentally unfit for such a strain.

4. CARDIAC DISORDER FUNCTIONAL, POSTINFECTIOUS

Individuals of this type date the onset of their cardiac symptoms very definitely to an attack of one of the acute infections which are known to affect the myocardium at times, such as pneumonia, influenza, meningitis, diphtheria, and streptococcus infections. In the patient seen during the acute illness, definite evidence of myocardial involvement sometimes can be demonstrated, if we can accept such findings as an enlarged area of dulness with alteration in force and rhythm, and the definite murmur of mitral insufficiency. After a few weeks these may disappear entirely to be succeeded by the negative picture of functional cardiac disorder. Seen first at this stage, a diagnosis of myocarditis cannot be made with positiveness. However, the majority probably are essentially of the functional type throughout. If such patients can be followed for a sufficient period, it is again possible that a certain proportion will develop evidence of a true myocarditis; but failure to find it six months after infection would warrant the belief that the symptoms of cardiac disturbance were dependent on other factors than irremediable myocardial degeneration. In a few doubtful cases the electrocardiograph has enabled us to differentiate true myocarditis, which would have been difficult to determine on purely clinical evidence.

In the majority of these patients the physical findings are the same as in the other groups. Subjectively the dyspnea on exertion is the most prominent symptom, while precordial pain and vertigo are less frequent. The latter facts are in noteworthy contradistinction to the findings in myocarditis on the one hand, in which precordial pain is quite common, and to the neurotic or constitutionally or physically inferior types on the other hand, in which both precordial pain and vertigo are frequently encountered.

The determination of the line of duty of such disabilities offers no difficulties when they follow acute infections occurring while on duty. Much more difficult is the determination of the disability. Full consideration should be given to the individual who followed an active pursuit prior to enlistment and who carried on well during his military service until he contracted the infectious disease. He should be warned of the dangers of physical idleness on the one hand, and of over activity on the other. Under the worst of circumstances probably only a few will fail to revert to their former physical status, so that the compensation may safely be assumed to be "temporary."

How long to continue the physical training of these patients often is not easily determined. If proper facilities are available under suitable environment, and nostalgia from prolonged stay in hospitals is not a factor, many of them can be completely cured in from six to twelve weeks. For some, a "therapeutic furlough" restores morale and enables them to undertake the cure in an adaptable frame of mind. In not a few of these postinfectious cases, the history of events before enlistment and the presence of certain characteristics found in the group of the "constitutionally inferior" or in the type of the "defective physically" show that they were substandard even before the acquired infection. For such patients disability need not be large if their previous occupation has been light or sedentary, since their physical handicap will not weigh heavily on their wage-earning capacity. The more closely they approach the constitutionally or physically defective type, however, the less the chance for improvement from the exercises.

5. CARDIAC DISORDER FUNCTIONAL, POSTRHEUMATIC

This special classification was made before the signing of the armistice, in the belief that no patient whose cardiac symptoms dated from an attack of rheumatic fever could safely be permitted to return to full military duty, no matter how slight the evidence of myocardial damage, as well as on account of the tendency to recurrence under conditions of active campaign. All the cases in this group were studied with especial care to determine valvular and myocardial lesions. In a large proportion, no more evidence of definite pathologic changes could be found than in the preceding four groups, so that we were forced to place them under the class of functional disturbances, although it is reasonably certain that some will develop later definite myocardial lesions. For this reason, their compensation should be more liberal for any active vocation, and the possible contingencies anticipated with the statement, "future problematical."

HYPERTHYROIDISM

We have had a comparatively small number of cases of true hyperthyroidism with persistent tachycardia, nervous unrest, turgescence and enlargement of the thyroid gland, marked tremors, more or less exophthalmos, and, above all, increased basal metabolism. Since treatment of true exophthalmic goiter, apart from surgical interference, primarily consists of complete physical and mental rest, while the worst thing that can be done for a victim of functional cardiac disorder (as Lewis points out) is to be put to bed, the differentiation of the two diseases is of vital importance from a therapeutic standpoint. This subject has been considered in an article by Major Peabody, which is in process of publication and need not be considered here. The disability resulting from true exophthalmic goiter should be absolute with the prospect, naturally, that full compensation will not be needed indefinitely.

MIXED TYPES

Not a few cases have been of a mixed type, when constitutional inferiority, defective physical development, and neurotic characteristics have all figured prominently in the patient's antecedents. These cases offer diagnostic difficulties; but disability and compensation are decided on the basis of the kind and amount of military duty performed, rather than on an academic accuracy of differentiation. We have had very little experience with the disturbance of cardiac action that follows exposure to gas, although the history at times showed a clear-cut etiologic relationship. A separate study of gassed patients has been instituted.

ORGANIC HEART DISEASE

The description of these cases needs no special consideration. As usual, it is found that acute rheumatic fever, both before and after enlistment, figures largely as an etiologic factor. Several instances illustrated the perfectly well recognized, but not yet sufficiently known fact that the valvular lesion itself plays a negligible rôle in producing symptoms, so long as the myocardium is competent. The iron-worker or stevedore with valvular disease may accomplish his heavy day's work for years in absolute ignorance of his impending disability. One noteworthy case gave a history of a severe attack of rheumatic fever two years before enlistment. Subsequent to this he worked as a boiler-maker without any apparent cardiac embarrassment. Two months after enlistment, having been examined and accepted in Class A, he experienced an attack of suffocation with some blood spitting while on a march with full equipment from Brest to his regimental billets. At the time he was suffering from a "cold," but otherwise he had been perfectly well since enlistment. After a day's rest he recovered, but seven days later while at drill he had another and larger hemorrhage and was finally invalided home. We found a typical mitral stenosis, which, it is reasonably certain, had originated in the attack of rheumatism some two and a half years previously.

In the preparation of his certificate for discharge, the disability was put "not in line of duty," for the obvious reason that the length and type of service had been too short to produce such disability in any but a potentially ill man. The reviewing authority requested that this decision be reconsidered on the basis of the wording of General Order 47, War Department, which provides that any determined disability which occurs subsequent to a soldier's enlistment, after he has been examined and passed, shall be considered in line of duty, unless it can be shown unmistakably that the disability existed prior to military duty. The use of the word "disability" instead of "disease" offers ample opportunity to compensate a soldier who has been rendered hors de combat by cardiac disease.

The actual and relative number of instances of aortic regurgitation in overseas patients has been surprisingly large. Two explanations for this can be offered: first, that mitral murmurs are less easily overlooked, and consequently that their possessors are rejected, and second, that the stress of intensive training and the even greater stress of actual conditions of battle have aggravated lesions that were in their incipiency at the time the soldiers enlisted. In the absence of the concomitant signs usually found in this disease, the interpretation of a definite diastolic murmur at the left sternal border is open to some question, but can hardly be decided on any basis other than that of aortic insufficiency. Apparently this soft diastolic murmur is very frequently missed. The question has arisen as to the possibility of cardiorespiratory murmurs occurring during diastole when the patient checks his respiratory movements at the end of expiration. In one instaance of functional cardiac disorder in a thin-chested individual, a systolic cardiorespiratory murmur could be heard at the apex during respiration, but disappeared on the patient's holding his breath. In the same individual a distinct diastolic murmur was heard over the sternum at the end of both inspiration and expiration. This was atypical in time and quality and variable in intensity, however, and was undoubtedly produced by exocardial factors.

We have encountered two instances of congenital heart disease:

The first, patulous ductus arteriosus, occurred in an officer whose first cardiac symptoms of which he had any recollection occurred at the age of 8, consisting of pain around the heart felt chiefly on deep inspiration. At school he was unable to play games vigorously without dyspnea and the precordial pain, but the disability was so slight as not to interfere with his work later as a laboratory worker and veterinary surgeon. In July, 1917, he was examined and passed for military service; did full duty in this country in the veterinary corps; was sent overseas in March, 1918, and continued to do full duty until September 15, when under fire and the coincident excitement he developed an extreme cardiac palpitation, dyspnea and nervousness, for which he was invalided home. When he entered this hospital, November 8, he was feeling perfectly well when quiet, but complained of some dyspnea and palpitation on exertion. Examination of the heart showed the point of maximum intensity in the fifth interspace 9.5 cm.; left border, 10 cm. in the fifth interspace; right border, 3 cm. in the fourth interspace from the midsternal line. There was an almost continuous "humming-top" murmur, loudest during systole, heard best in the third left interspace, transmitted for some distance to the left and upward. The pulmonary second sound was accentuated in the recumbent position, and a soft systolic murmur was heard at the apex. There was practically no cyanosis except after exercise. After nearly two months of rest the condition of this patient is apparently the same as before he entered the Army.

The second patient was an enlisted man who claimed that he had never suffered any disability and had worked in an iron foundry for eight months before enlistment. In June, 1918, two months after induction, he developed his first symptoms—dyspnea, cough and weakness—while on a hike from the port of debarkation to his rest billets. On admission to this hospital in October, the area of cardiac dulness was not enlarged; there was slight accentuation of the second pulmonic sound and a rasping systolic murmur, loudest at the third left interspace close to the sternum, diminishing to a rather faint murmur at the apex and transmitted well to the left along the third and fourth ribs. There was no cyanosis nor any history of it. A diagnosis of defective interventricular septum, small lesion, seemed the most probable. The disability was rated with that of mitral regurgitation.

In spite of all that has been written, the fact still needs emphasis that most systolic murmurs at or near the apex are of functional, rather than organic, origin. In spite of many exceptions, the organic murmur is loudest at or near the apex, is constant, and is increased by exercise; and the functional murmur is apt to be as loud or louder at the base and is exaggerated in the supine position. To exclude cardiorespiratory murmurs, auscultation should always be done with the patient holding his breath midway between expiration and inspiration. Enlargement of the heart, making due allowance for the size of the individual and the shape of the heart and the chest, points to the organic lesion. Marked accentuation of the second pulmonic sound and transmission to the left axilla are significant but by no means infallible criteria. A few cases will almost elude analysis. In these, the previous occurrence of rheumatic fever often will turn the scale in favor of the diagnosis of an organic lesion. In general, also, we have observed that the acceleration of the heart's action, both at rest and after exercise, is less in the case with the true organic lesion than in the functional disorder.

The typical presystolic murmur of mitral stenosis would rarely be missed if the heart were ausculted with the patient lying down. This is of sufficient importance to warrant the use of examining tables. The only disadvantage would be the misinterpretation of the accentuation of the functional systolic murmur in the supine position. The differentiation of the Flint murmur with aortic regurgitation from that of a coincident mitral stenosis usually can be made on the crescendo character ending in the snapping first sound. At times, however, the distinction is difficult to make. The stenotic murmur usually is sharply localized at or just to the right of the point of maximum intensity. The Flint murmur has a wider distribution, at times extending even to the left border of the sternum. Both the aortic regurgitant and the Flint murmurs are heard better, as a rule, in the erect than in the supine position, while the murmur of mitral stenosis is affected in the reverse order. Definite enlargement at the base of the heart would be prima facie evidence of stenosis. Unfortunately, this is difficult to determine with accuracy, and even the orthodiagraphic plates are misleading in many instances. When all physical findings are inconclusive, the probability may be assumed that a double lesion would produce more disability than simple aortic insufficiency, unless the valvular lesions were of recent origin.

Pericardial lesions have been recognized in only a few cases. In one case which resulted from a high explosive shell wound with a definite history of a suppurative lesion, the only residual signs were a short and sharp first sound without murmurs, and a definite fixation of the heart on change of position. Another case had been diagnosed on the presence of well marked enlargement and Broadbent's sign. Mitral insufficiency was also evident, but was thought to be due to old valvulitis. This patient was killed in an automobile accident, and the diagnosis of pericarditis was confirmed at necropsy. The mitral leaflets were absolutely normal, however, and the insufficiency was purely relative.

In the majority of the cases we have seen, the valvular disease undoubtedly existed at the time of enlistment, and was overlooked by the examining surgeon. The disability which succeeded after several months of military duty therefore was considered to be in line of duty. In determining the degree of disability with a view to compensation, there should be due consideration for the expectancy of life and ability to continue in a wage-earning capacity, as well as for the type of work of which the soldier is capable. It is believed to be the intention of the Federal Board for Vocational Education to compel the soldier to take advantage of opportunities for learning a new trade, by refusing compensation for total disability in the case of a soldier who is physically able to carry on a lighter occupation after instruction, but is unwilling to take the instruction. Until the machinery for this is in good working order, it is manifestly unfair to the soldier to penalize him by compelling him to continue a laborous pursuit because compensation is not sufficient to enable him to live without it, so that disability should cover these needs, until provision can be made for vocational reeducation.

OCCUPATION

We have emphasized the importance of the history in determining the types of functional cardiac disease, and one of the most important items in the history is the previous occupation. In the series so far reviewed, over 60 per cent. of those with functional cardiac disease have earned their living in prewar days in light or sheltered occupations. Of the organic cases, over 80 per cent. have selected active economic pursuits, in spite of the more or less damaged condition of their hearts. As Major Peabody has elsewhere pointed out, those with functional cardiac disease always take particular care not to injure themselves by hard manual labor. The much more unfortunate victim of organic heart disease does not hesitate to take chances, in spite of great limitation of his cardiac reserve.

EXERCISE

We must emphasize the fact that our studies have demonstrated beyond reasonable doubt that the individual suffering from functional cardiac disorder of any type does better on exercise than on rest; that the exercise must be graduated from the smallest possible beginning, and that these patients require constant encouragement to overcome their natural aversion to, and fear of, the symptoms produced by exertion. These symptoms have resulted in their leading inactive lives until the vicious cycle has been definitely established. The cycle cannot be broken successfully by revolutionary methods. As has been stated, many of them fail to respond to any discoverable incentive. A few react to the gospel of muscular development, and it is an interesting speculation as to how many might have been saved a lifelong disability had the gospel been rightly preached at the impressionable age. The neurotic type is too self-centered and neurasthenic to be reached in ordinary class work. The approach to this individual must be psychiatric as well as physical. The postinfectious type offers the greatest possibilities for real cure, with the proviso that especial care must be exercised to avoid overstrain. True myocardial lesions in the light of our present knowledge demand rest until all definite signs have disappeared. Finally, it must be noted that graduated exercise offers a much better cardiac tonic for cases with valvular defects than years of clinical teaching have led us to believe. It cannot be too strongly insisted, however, that the fool rushing in where angels (of the past) feared to tread may work incalculable damage. Caution and skilled knowledge are prerequisities of successful treatment.

Tuberculosis.—Tuberculosis is the great scourge of civilized mankind. Unless more progress is made in fighting the disease, 9,000,000 of the 100,000,000 persons in the United States may be expected to die of it.—*Health Bulletin*, Newark, N. J.

BACTERIAL PROTEIN INJECTIONS IN INFLUENZAL PNEUMONIA *

DUDLEY ROBERTS, M.D. (Brooklyn)
Major, M. C., U. S. Army; Chief of Medical Service
AND
EDWARD G. CARY, M.D. (New York)
Major, M. C., U. S. Army; Chief of Laboratory Service
WILLIAMSBRIDGE, N. Y.

During the early days of the recent pandemic of acute respiratory disease, it became evident that we were dealing with a new and exceedingly fatal malady. In many cases it was obvious from the first onset that the peculiar widespread pulmonary pathologic condition was already established and that death was certain. In other cases we helplessly watched the sudden or gradual change from a mild type of the disease and from a limited pathologic process to the virulent form with the usual outcome. All therapeutic efforts seemed futile, the condition of our vigorous young patients changing for better or worse in the most puzzling manner. Desultory attempts were made to save life by phlebotomy and hypodermoclysis or by drugs supposed to effect a proper balance in the pulmonary circulation. Patients were accurately digitalized, but, while the heart action remained excellent, the end was only postponed. Transfusion of blood from recovered patients was tried in a few instances with unsatisfactory results. However, only the worst type of case was selected, and our experience with the procedure in lobar pneumonia strongly suggests that in a series of cases the results might be excellent. Hypodermic administration of mixed influenza, pneumococcus and streptococcus vaccines was tried in a well-controlled series of influenza cases as soon as possible after admission. The percentage of pneumonia and the mortality in this series was no lower than in the series of cases alternately admitted and used as controls. The results might have been different had a dosage been used sufficient to excite the phenomena that followed the intravenous injection of the same preparation.

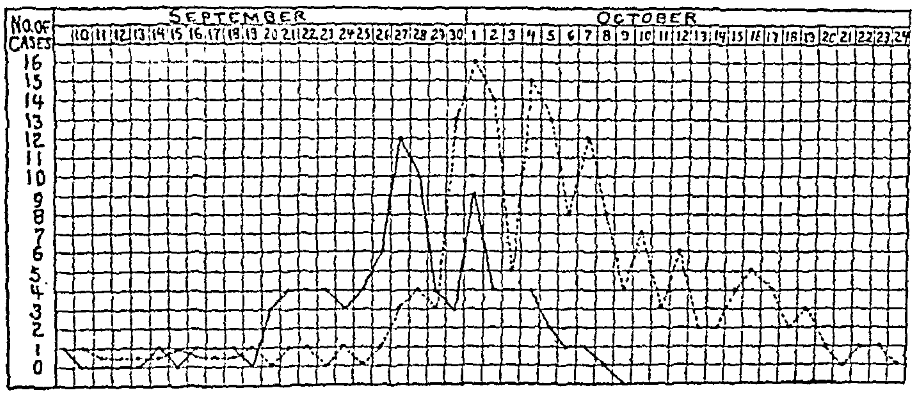

Chart 1.—Incidence of onset of pneumonia: solid line, Series 1; broken line, Series 2.

October 3, we began the use of intravenous injections of mixed influenza vaccines in a consecutive series of cases, varying slightly the dosage and the mode of procedure as experience accumulated. Chart 1 shows the incidence of the onset of the disease in the two series from the beginning of the epidemic to the conclusion of this study. Each series of cases is entirely made up of definitely established pneumonias. Patients were admitted either directly from the receiving ward with pneumonia already developed, or were held in the influenza wards until consolidation was definitely established. No cases were excluded from either series because of the hopeless condition in which the patient was when admitted, some in each series dying in a few hours.

It was at first thought that by the use of these mixed vaccines a specific immunity might be quickly established against what we believed were the secondary invaders, namely, the pneumococci and streptococci. We soon found that in spite of the establishment of massive consolidation, good results were obtained when there was a definite reaction following the injection, and we came to believe that we were largely dependent for results on a "nonspecific protein" reaction. We felt, however, that the use of a vaccine made from the prevalent organisms was advisable for many reasons, and no observations were made with other forms of protein.

THE VACCINE OR BACTERIAL PROTEIN

A saline suspension of heat-killed organisms was used, so that each cubic centimeter contained 100 million influenza bacilli; 100 million pneumococci, Types I, II and III; 100 million streptococci and 100 million staphylococci. So far as exciting an active immunity is concerned, it is apparent on studying the bacteriology of the disease, as seen in the accompanying table, that streptococci and pneumococcus Type IV were frequently present, and the vaccine was probably not sufficiently polyvalent because of our inadequate knowledge of these strains. At the outset we used 0.5 c.c. as the initial dose, and doubled the dose daily until four doses had been given. Later we used 1 c.c. as an initial dose and regulated the succeeding doses by the amount of reaction. We were anxious to secure a sharp reaction, and the dose was increased or held the same according to the character of the reaction secured.

THE REACTION

The characteristic reaction following injections is seen in Charts 2 and 3. About one-half hour after the injection there is a chill or chilly feeling accompanied by a definite rise in pulse rate. In from one-half to two hours later there is a rise of temperature of from 1 to 3 degrees depending on the previous level. The elevation of temperature is always of short duration and is easily overlooked unless the temperature is taken at least every half hour. The fall of temperature may be only slight, but at best it is a crisis, reaching practically normal. Elevation in a few hours may occur after several falls until finally the temperature continues normal. During the chill the patient is not particularly uncomfortable, and when it is over and the temperature falls there is a definite improvement in the state of well-being. From our experience with over 200 cases treated by protein injections, it may be positively stated that there are no untoward results whatsoever. The severely ill are never made worse.

While it is true that the results are unsatisfactory if a reaction does not follow the injection, and that

---

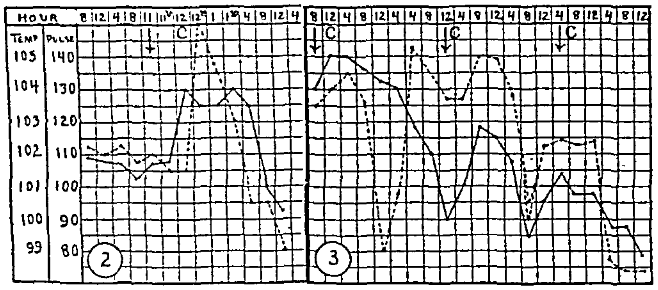
* From the United States Army General Hospital No. 1 (Columbia War Hospital).

the results are usually satisfactory if there is a sharp reaction, these rules are not without exceptions.

Charts 4, 5 and 6 give daily reports of the course of the temperature before and after the injections in some particularly severe cases. Under expectant plans of treatment, judging from bedside observation and the extent of the pathologic process as shown by roentgenograms, cases such as these always ended fatally. By this form of chart the true relation between injection and temperature rise and fall is not explicitly conveyed.

RELATIVE MORTALITY

In Series 1, with expectant treatment, out of a total of eighty-six cases there were twenty-seven deaths, a mortality of 31.2 per cent. In Series 2, treated with protein injections, out of a total of 200 cases, there were nineteen deaths, a mortality of 9.5 per cent. The question arises at once as to whether the lowered mortality in Series 2 was due to the fact that it was later in the epidemic. In Chart 1 is shown the incidence of the onset of the cases in each series. It is shown that while the two series were not parallel, they overlapped to a certain extent. Taking the period up to and not including October 5, there is sufficient overlapping to permit of a fair comparison. In Series 1, eighty-three cases had their onset with a mortality of 31 per cent., and in Series 2 sixty-seven cases must be included, with a mortality of 11.3 per cent. This is graphically demonstrated by Chart 7. The mortality after October 5 was slightly lower, but this may perhaps be accounted for by improvements in the technic of administration. There appear to be no reasons for believing that there was a difference in the virulence of the cases included in the two series, although later on, during November and December, the virulence seemed to be somewhat lessened.



Charts 2 and 3.—Effect of protein injection on pulse and temperature: solid line, pulse; broken line, temperature; arrows indicate protein injections; C, chill. In Chart 2 the records were made at frequent intervals; in Chart 3 there was failure to catch the maximum rise owing to taking the temperature only every four hours.

RESULTS OF SPUTUM EXAMINATION IN INFLUENZAL PNEUMONIA

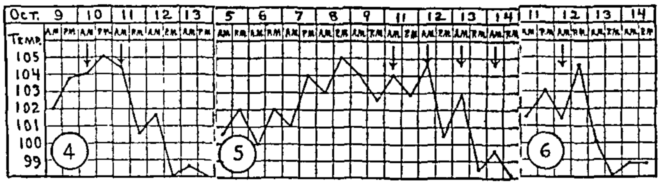
Percentage......		56%	25%	0	5	5	60%	22%	1%	36%

RECOVERY BY CRISIS

Usually the temperature returned to normal by lysis. In the first series, crisis occurred in 20 per cent. of the cases, while in the second series the temperature came to normal by crisis in 36 per cent.

COMPARISON OF DURATION OF THE DISEASE

In Chart 8 is shown the percentage of cases reaching normal temperatures on the various days after admission to the hospital. Had the injections not been withheld until the diagnosis was definitely established, the differences might have been even more striking. As it is, there can be no question that convalescence, as judged by the return of temperature to normal, came earlier in the protein injection series.



Charts 4, 5 and 6.—Course of temperature before and after injections in particularly severe cases: arrows indicate protein injections.

EFFECT ON THE LEUKOCYTE COUNT

The press of work precluded elaborate studies of the leukocytes before and after injections, but in a table prepared but not given here, the results in nine cases are shown. The rise was transitory, varied in its maximum, and was not always caught if, indeed, it was present. The increase was polymorphonuclear, and at no time was an eosinophil increase observed.

THE STATUS OF NONSPECIFIC PROTEIN THERAPY

The idea of using injections of bacteria and foreign proteins in the treatment of disease was forced on our attention largely by the excellent results reported from the use of typhoid vaccines intravenously in the treatment of typhoid fever and by the fact that later equally good results followed injections of other organisms. Since then a variety of proteins have been used and suggested, but the chief use has been made of the idea in the treatment of arthritis by typhoid vaccines. Apparently something happens as a result of the reaction following protein injections. Gay and Claypole, and others since, have called attention to the rise in the leukocyte count incident to the reaction. Various investigators have seemed to prove that there is a higher agglutinin and lysin production in animals subjected to high temperatures. Others have shown that the opsonin and lysin content of human and animal serum is definitely raised after the therapeutic injection of foreign protein. We have ourselves observed the most striking results in the prompt recovery of patients following the use of therapeutic serums when the amount given was so small that a passive immunity was out of consideration. Herrmann[1] in a recent summary of the subject concludes that "the intravenous

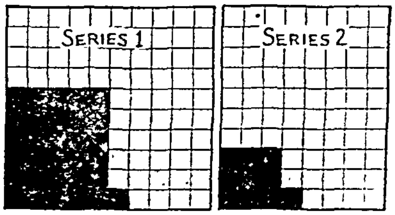


Chart 7.—Mortality (indicated by solid black): In Series 1 there were eighty-three cases with onset to October 5, and the mortality was 31.2 per cent.; in Series 2 there were sixty-seven cases with onset to October 5, and the mortality was 11 per cent.

[1] Herrmann, S. F.: Liberation of Antibodies on Injection of Foreign Proteins, J. Infect. Dis. 23:457 (Nov.) 1918.

injection of foreign protein serves as a stimulus for the liberation of specific antibodies in animals in which the previously injected antigen was unable to cause such a liberation." In other words, while the therapeutic injection is nonspecific, the antibody response is specific.

The invasion of pathogenic micro-organisms excites certain symptoms or phenomena that are intimately associated with the development of immunity. Experience, at the present time, with the reaction following protein injections tends to show that the repetition of these phenomena, or their accentuation during the course of a disease, is followed, in many instances, by striking clinical results. Much remains to be done to determine the most desirable kind of protein and dosage. Aside from the dangers attending intravenous medication, it may again be emphasized that the procedure is harmless. Bacterial vaccines are always available in safe and convenient form, and a protein reaction may be secured by subcutaneous or intramuscular injection if a dose several times as large as the ordinary is used. Bacterial vaccines commend themselves because there is no danger of anaphylactic sensitization as is the case with many foreign proteins. Sterile milk is an admirable form of protein for intramuscular injection, but there is always a possibility of sensitization.

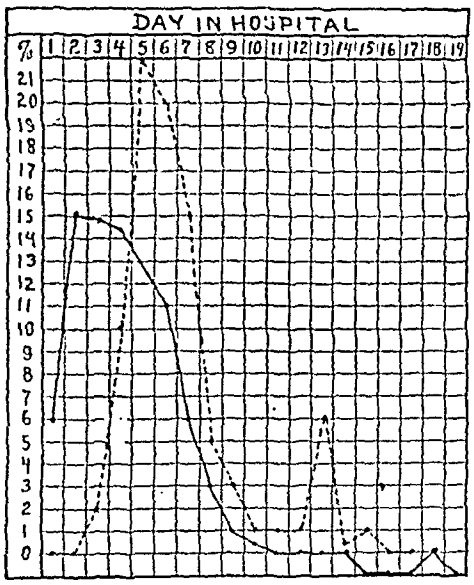

Chart 8.—Percentage of cases reaching normal temperature on days after admission to the hospital: broken line, Series 1; solid line, Series 2.

In studying and recommending any new therapeutic procedure, the greatest caution should be observed. We have endeavored critically to analyze our results and see to what other factors the shortening of the disease and the lessened mortality in our series of cases might be due. We have been forced to conclude that, in the malady under consideration, protein injections have a very definite therapeutic value, and we are inclined to believe that the procedure will come to be accepted as useful in a wide variety of infectious diseases.

Menthol.—Japan is one of the greatest producers of menthol and peppermint. According to Consul-General George H. Scidmore at Yokahama (*Commerce Reports*, February 28), the crop during the past year has been poor, the acreage of mint having been reduced by about 50 per cent. on account of the low prices prevailing in 1917. In 1916 the trade reached its height, most of the product coming to the United States instead of to Germany as before the war. Owing to conditions of shipping and other factors connected with the trade, the price began declining in 1917, and though the export in that year amounted to 332,275 pounds, valued at $793,975, the total for 1918 to the end of September amounted to $35,183 less than for the same period of 1917. The price had been steadily decreasing until the end of the war, when prices began going up; and at the time of this report had reached $7.73 per kin of 1.32 pounds, almost twice the lowest price reached in 1918. In the early part of 1918 the crystals were quoted as low as $2.50 and the oil at 90 cents per kin.

GROSS PATHOLOGY OF EPIDEMIC INFLUENZA AT WALTER REED GENERAL HOSPITAL

M. W. LYON, Jr., M.D.
Captain, M. C., U. S. Army
WASHINGTON, D. C.

In this paper is given a brief account of the gross pathologic changes seen in fifty-six necropsies of cases of epidemic influenza between Sept. 18 and Nov. 17, 1918, at the Walter Reed General Hospital. Within the next month only four other cases of influenza were examined at necropsy. These differ in no essential manner from the fifty-six cases of this summary, except that one became a Type I pneumococcus septicemia, pneumonia and double empyema, and resulted fatally sixty-four days after the onset of the original attack of influenza. Another developed a massive bilateral serofibrinopurulent pleural effusion and a fibrinopurulent pericarditis. I performed practically all of the necropsies. In a few I acted as an assistant. The account is based on an examination of the protocols of the necropsies rather than on general impressions as to the findings. There is no essential novelty in the findings, but as some of the gross changes differ slightly in kind and frequency from those seen in other localities, it would appear worth while to describe them. The cases came from military camps in the immediate vicinity of Washington, from men on duty in the city proper, or men stationed at the hospital. The first case coming to necropsy and recognized as epidemic influenza was from the Quartermaster Corps at the hospital. A week later the epidemic began in earnest. In addition to the gross necropsy findings there is included in this summary the leukocyte counts and the urinalysis of these fatal cases so far as they were made.

Part of the bacteriologic findings in this series of cases have already been reported on by Nichols and Stimmel.[1] When they seem of particular interest in these notes, the bacteriologic results are given. The bacteriologic studies were all made by these two authors. Bacteriologic examinations have yielded a variety of organisms from the lungs, pleural fluids, etc., among them pneumococcus, all groups but II, most frequently, Friedländer bacillus, influenza bacillus, hemolytic streptococci and staphylococci. No one form was found constantly present. Among many blood cultures, mainly antemortem, influenza bacilli were never recovered. The only locations in which this organism occurred were the lungs, bronchi or trachea, and the organism was obtained either antimortem or postmortem. It was isolated comparatively infrequently in this series of necropsies, and was never found to the exclusion of other bacteria, although late in the epidemic it was obtained rather consistently by lung puncture from patients.

DAY OF DEATH AFTER ONSET

The average duration of life from the date of onset was 12.4 days. The shortest illness was 3 days and the longest 35 days in a case of pneumococcus empyema. The average day of death in September with seven cases was 8.5 days; during the first half of October

1. Nichols, H. J., and Stimmel, C. O.: Pneumobacilli as Complicating Organisms in Influenzal Pneumonia, J. A. M. A. **72**: 174 (Jan. 18) 1919.

with twenty-four cases, 10.3 days; during the last half of the month with seventeen cases, 13 days; and during November with four cases, 17.7 days. The increasing length of life after onset in the later cases is probably due not so much to greater virulence of the virus in the earlier cases as to the fact that those not succumbing in the early onrush lived to die of secondary invaders.

APPEARANCE OF BODY AFTER DEATH

The appearance of the body was in most cases characterized by a cyanotic condition of the neck, the ears, and the adjacent portion of the face and the shoulders. Equally conspicuous was a brownish or reddish brown fluid about the nostrils and the mouth. Often when the body was turned on its side, a large quantity of this reddish brown fluid, often frothy, drained from the nose and mouth. Of the fifty-six necropsies, only eight are recorded as not showing these conditions. In six cases, universal icterus of greater or less degree was present. Most of the necropsies were done on individuals who appeared to be between 20 and 30 years of age; about five appeared to be between 30 and 40. As the army is composed of young men, this excess of young adults is not surprising. Of the fifty-six cases, thirteen are referred to as of slender or less than average build, all the others being well built; but this proportion is probably no greater than the normal ratio of slenderly built and well built men in the service.

LEUKOCYTE COUNT

The average number of leukocytes per cubic millimeter in this series of fatal cases was 5,537, with extremes of 2,675 and 11,900. Nineteen were less than 5,000; seventeen between 5,001 and 7,500; four between 7,501 and 10,000, and three over 10,000. These figures include only the low counts, and disregard a number of high counts occurring at a period later in the disease when secondary infections were evidently in sway, such as 11,300 at twenty-one days; 12,600 at thirteen days; 15,450 at twenty-one days; 16,630 at thirty-five days; 22,100 at twenty days, and 30,300 at seventeen days.

CHANGES IN THE LUNGS AND ACCESSORY STRUCTURES

Hemorrhagic Pneumonitis.—This term is used to designate one of the characteristic lesions of the disease, and seen in all the cases. It was marked by intense congestion of the lung tissue and an abundance of serous fluid loaded with red cells in the alveoli. It was present in all lobes, and nearly always most conspicuous in the lower lobes and toward the mediastinal sides. In no instance did the process involve completely any entire lobe. Close examination revealed, in every case, air-containing areas. In the lower lobes, which were most involved and often appeared nearly solid, there were nearly always found along the anterior border of the lobe and even along the lower borders air-containing portions, usually emphysematous. These borders often appeared as a distinct air-containing edge. At other times they contained air-containing lobules, single or in groups. Sometimes in the midst of an almost solid portion of a lobe were found single air-containing lobules. The edges of the hemorrhagic areas in air-containing portions and of air-containing areas in the hemorrhagic portions were nearly always sharply defined. In three instances the hemorrhagic pneumonitis was essentially confined to one side, the left. In two instances the process was more pronounced in the upper lobes than in the lower. In no instance was the right lung involved when the left was not. In probably about half the cases the upper lobes were almost as extensively involved as the lower lobes, and their air-containing portions were emphysematous. Apparently the only reason why the entire five lobes of both lungs were not uniformly involved was that death necessarily occurred from lack of air before so complete an involvement could take place. It was surprising to see how extensive the lung involvement was and realize that only a few hours previously the condition must have been nearly the same while the patient was still living. On the other hand, there were cases in which the hemorrhagic pneumonitis was not extensive enough by itself to have caused death. The lobe least frequently involved was the right middle. In eight cases it was essentially uninvolved, of the fifty-three cases in which the right lung was attacked.

The distribution in the lungs of the hemorrhagic pneumonitis was very similar to the congested areas in the lungs seen so frequently in death from various causes. One cannot escape the conclusion that the hemorrhagic pneumonitis was in some manner connected with posture and the so-called hypostatic congestion of the lungs; but that this is not entirely so is shown by those cases, comparatively few, however, in which the hemorrhagic process was more pronounced in the upper lobes than in the lower.

Pneumonic Processes.—A more or less distinct consolidation was usually present somewhere in the lungs, although in eleven instances (20 per cent.) no real pneumonic process was observable, the only lung lesion being the hemorrhagic pneumonitis. The average day of death in these eleven cases was 7.7, with extremes of 3 and 16 days. The pneumonic process as here understood consisted of larger or smaller areas of distinct consolidation, varying in color, being light gray, brownish gray, or dark reddish brown. When the more grayish portions were scraped, considerable purulent material was usually seen. In thirty-five of the cases the consolidated portion was of small size and might be termed a lobular pneumonia. This lobular process occurred no more frequently on one side than on the other. Most often it was found in all the lobes, but was most pronounced in the lower lobes. In a few cases the lower lobes were the only ones involved. In sixteen cases the pneumonic process was extensive enough to be of a lobar type of consolidation. These lobar types of consolidation did not appear to be typical of lobar pneumonia as a primary disease. In no case was an entire lobe uniformly solid, but in many instances fully three fourths or two thirds of a lobe was involved. Nine of these lobar types were associated with a lobular type of pneumonia elsewhere in the lungs. Usually the lobar type appeared to be a confluent lobular pneumonia rather than a true lobar type of pneumonia. It occurred six times on the left side alone, and four times on the right side alone. In the six remaining cases this lobar process involved both lungs. While usually more frequently found in the lower lobes, the lobar type of pneumonia was occasionally seen in an upper lobe, when the lower lobe was not involved.

Other Lung Conditions.—In the instance in which a streptococcus empyema developed, the right lung is described as having tissue around the bronchi apparently infiltrated and of a light color—interstitial bronchopneumonia. Cultures from this lung yielded *Streptococcus hemolyticus* and Friedländer's bacillus. The same organisms were found in other lungs not showing this condition.

In one necropsy with lobar pneumonia in the right upper lobe and lobular pneumonia elsewhere in the lungs, pressure on the lung substance at various places expressed a small drop of thick, creamy pus from the cut bronchioles. This was the only instance in which this condition was seen, although there were five cases in which purulent material was found in the larger bronchi.

In one instance, cross-section of a portion of lung with marked hemorrhagic pneumonitis, the structure was slightly honeycombed with small bubbles resembling somewhat the liver in experimental gas bacillus infections in animals.

Emphysema of most of or at least some part of the air-containing portions of the lungs was always present. Sometimes the distention of the air vesicles was very marked. Interstitial emphysema was very rare. In three instances there were small bubbles of air or gas in the mediastinal tissue, a condition sometimes seen in any necropsy, and apparently in no wise associated with influenza. In two instances there was an apparent escape of air beneath the pleura, raising it up in a few places. By direct pressure these "bubbles" beneath the pleura could be pushed from one part of the lung surface to another. In a number of cases there appeared to be air-containing lines in or beneath the pleura, more or less roughly outlining the lung lobules. These were interpreted as small, once distended but now empty vessels. Aside from these few scarcely noticeable instances of interstitial emphysema, such a condition was not seen. Extensive accumulations of gas beneath the tissues anywhere, such as has been reported by some observers in other localities, was not seen.

No lung abscesses were found. In many cases, had the patient lived, abscesses would have in all probability formed; but in only one instance was there any indication of a distinct softening of any of the consolidated portions of the lungs, and that particular area was solitary and of small size.

Weight of Lungs.—The lungs were usually much increased in weight, owing to pneumonic and hemorrhagic processes or both. The average weight of both lungs together, including a few millimeters of trachea, was 1,953 gm., with extremes of 775 and 3,290 gm. In case each lung was removed separately, a portion of the trachea was always left attached to one. The unusually light pair of lungs came from a very slightly built individual who had a marked lateral curvature of the spine and an unusually small thoracic cavity, and in whom only the left lower lobe was extensively involved in the hemorrhagic pneumonitis. In the case of the pair with the maximum weight, the right lung was very much enlarged and almost uniformly solid; its weight by itself was 2,740 gm. In about half the necropsies, the lungs were removed attached to each other and used as museum objects. In the half in which they were removed and weighed separately, the average weight of the left lung was 870 gm. with extremes of 550 and 1,320 gm. The minimum occurred in the left lung of the pair that weighed the most. The maximum weight of left lung occurred in one having a distinct lobular pneumonic process in addition to the hemorrhagic pneumonitis. The average weight of the right lung was 1,118 gm., with extremes of 650 and 1,560 gm. The lightest right lung occurred in the first case of influenza coming to necropsy, and showed a hemorrhagic process in the upper and lower lobes but not in the middle. The lung was not weighed until after it had been sectioned and lost much blood. The heaviest right lung showed large areas of lobular consolidation and an extensive hemorrhagic process involving all the lobes. The pair of lungs in this instance was the second heaviest pair, being 2,980 gm. in weight. After these two lungs had been cut apart and each was weighed separately, the combined weight of both lungs was then only 2,880 gm., 100 gm. of red, frothy fluid having dripped from the bronchi and trachea. This loss of weight by draining of fluid from the lungs after they were cut apart or sectioned was always considerable, but it was recorded in only a few instances. In one case as much as 400 gm. were lost.

Trachea and Larger Bronchi.—On cutting across the trachea or the main bronchi in essentially all cases, a large amount of reddish or pinkish frothy fluid dripped out; in some cases the fluid was so abundant that the trachea resembled a large blood vessel when cut across. In five cases the fluid dripping from the trachea or bronchi was purulent, and in one case it was mucopurulent. The mucous membrane of the trachea and bronchi was nearly always markedly hyperemic and appeared swollen and deep red, this color being most marked in the intercartilaginous portions. In one case the mucosa was of nearly a normal pinkish gray, but marked with some hemorrhagic spots. Occasionally in some with a hyperemic mucosa there were hemorrhagic spots.

Bronchial Lymph Nodes.—The bronchial lymph nodes were in most cases (thirty-five) enlarged and swollen to a greater or less degree. In a few cases the enlargement was considerable and the nodes soft and edematous, attaining dimensions of from 25 to 30 mm. In five cases the glands are recorded as not enlarged. In the remaining cases they attracted no notice, and were probably normal in appearance.

Hemorrhagic Pleuritis.—One of the more or less striking, essentially constant gross lesions of influenza was what may be termed hemorrhagic pleuritis. By this is meant a bright or dull red spotting seen through the pleura on the surface of the lung. It appeared to be an extravasation of blood beneath the pleura, or else an extensive and local dilatation of the vessels of the surface of the lungs. These spots varied in size from those of a pin point up to spots of 5 or 6 or 10 mm. in diameter. They were irregular in shape, but in general round. The spots were usually more or less grouped together, and were frequently fused into large, hemorrhagic areas of several centimeters in diameter and of a very irregular shape. This subpleural hemorrhagic spotting might be found on any part of the lung. They were less commonly seen on the upper lobes. Sometimes they were much scattered and few in number, so that they were seen only on close examination. Frequently they were present in large numbers on the diaphragmatic surface of the lungs. They were about as common on the interlobular surfaces of the lungs as on the external surface. The interlobular spotting was more abundant, as a rule, toward the root of the lung than toward the periphery. When fibrinous deposits were on the surface of the lung, these subpleural hemorrhagic spots were frequently found beneath them. They were never found on the parietal pleura. The latter, as a rule, was markedly hyperemic.

Pleural Fluids.—The amount and location of the effusion is shown in the accompanying table.

AMOUNT AND LOCATION OF EFFUSION

	No.	Per Cent.
No effusion on either side	9	16
Effusion present only on left side	23	41
Effusion present only on right side	16	29
When effusion was present on both sides it had the same volume on both right and left sides	4	7
It was larger on the left side	24	43
It was larger on the right side	19	34

When effusion was present, the average amount on the left side was 206 c.c., with extremes of 20 and 1,150 c.c., the latter occurring in a case of typical empyema. The largest nonpurulent effusion was 850 c.c. On the right side the average amount of fluid was 165 c.c., with extremes of 15 and 1,100 c.c., the latter occurring in a case of empyema. The largest nonpurulent effusion was 600 c.c. A definite pleural effusion was present in all but nine of the necropsies, or 84 per cent.

The pleural fluid was for the most part serous, and very dark or a light reddish brown, as though stained with blood pigment. In one instance the pleural exudate having a clear yellowish brown color appeared bile stained; this occurred in a case that showed marked jaundice. In many cases, fibrinous material was very evident and was found loosely adherent to the lung or to the chest wall. Nearly always, some fibrin could be found either as a few loose threads or as a scant deposit on the visceral pleura. In one instance the fibrinous deposit was a light dirty brown instead of the usual yellow, and was deposited in larger or smaller subcircular spots on the lung surface. The fibrinous material was often found deposited between the lobes of the lungs. In three cases the fibrinous material had a gelatinous-like quality, the exudate being quite transparent and the lungs appearing in places as though covered with thin patches of jelly. In eight cases the fluid was slightly or distinctly turbid, but not to such an extent that it could be called pus. In two cases the pleural exudate was purulent, and the condition of typical empyema was present.

Empyema.— Only two cases of the fifty-six (3.5 per cent.) developed a typical condition of empyema. The duration of one of these was twenty-one days. The presence of fluid in this case was not suspected either by physical signs or by roentgenography, and the presence of massive effusion, 1,150 c.c. left and 1,100 c.c. right, was a surprise at the necropsy. It was a fibrinopurulent exudate and entirely similar to the streptococcus empyemas seen during the winter of 1917-1918. The hemorrhagic pneumonitis had essentially disappeared from the lungs. Both lower lobes were atelectatic; the left upper lobe showed a bronchopneumnoia. Pneumococci were isolated from the pleural pus and also from the pericardial fluid, although the latter was clear and did not contain an excess of fluid. The other case was a right sided empyema, and during life a total of 2,120 c.c. had been aspirated. At necropsy an additional 200 c.c. of fibrinopurulent fluid was recovered. Cultures yielded hemolytic streptococci. In this case, death occurred on the seventeenth day. In several cases the pleural effusion was more or less turbid, but was not what would be called pus. The duration of the latter cases ranged from seven to twenty days following the initial onset of influenza.

CHANGES IN THE HEART AND PERICARDIUM

Pericardium.—None of the cases showed a fibrinous or purulent pericarditis. A moderate serous effusion was often present. Although the fluids were clear, they were often dark, as though somewhat blood tinged. The average amount of fluid was 21.7 c.c. Twenty-two cases had less than 10 c.c.; fourteen between 11 and 20 c.c.; twelve between 21 and 30 c.c.; one, 35 c.c.; three between 41 and 50 c.c.; two had 75 c.c., and two, 100 c.c. The pericardial fluids were so clear that cultures were seldom taken; but from the fluid in a case of pneumococcal empyema, pneumococci were obtained; and in a case of streptococcic empyema, *Streptococcus hemolyticus* was obtained. Pneumococci were also found in the pericardial fluid in one other case, pneumococci being isolated from the lungs as well. The visceral layer of the pericardium never showed any change except in one case, in which a few petechial hemorrhagic spots were seen on the left side. The parietal layer in four instances showed distinct hemorrhagic spots, one of these being the same case that showed the spotting in the cardiac layer. The spotting always occurred in the left side, and was associated with rather extensive subpleural spotting of the left lung.

Heart.—In the entire series the heart showed no evident pathologic changes. In twenty-seven protocols the right heart is mentioned as being moderately or slightly dilated, particularly the auricle, which was usually well filled with dark fluid blood. The right ventricle was much less distended. In nine cases the protocols state that the heart was not dilated. The matter is not mentioned in the other cases. The average weight of the heart in this series was 322 gm., with extremes of 210 and 460 gm.

A white thrombus starting in each ventricle and passing through the aorta and pulmonary artery was very frequently seen. It was long and thin, and as it passed the semilunar valves it had on it three small appendages of the same material as the thrombus, corresponding to each cusp of the semilunar valves. These thrombi gave the impression of an agonal formation and as perhaps being due to some increased coagulability of the blood.

CHANGES IN THE SPLEEN

Not many of the spleens could be called septic even though blood cultures yielded pneumococci or Friedländer bacilli. Twelve are mentioned as being either septic, enlarged and filled with soft dark semifluid material, or simply soft and with dark semifluid contents without being enlarged. The average weight of the spleen was 187 gm., with extremes of 85 and 350 gm. Three weighed less than 100 gm.; thirty-one, between 101 and 200 gm.; seventeen, between 201 and 300, and three over 300 gm. The organ usually felt firm and in general was a very reddish brown, because of congestion, though in a few cases it was comparatively pale.

CHANGES IN THE LIVER

The liver appeared rather pale, the color being mentioned as light yellowish brown as a rule. Even when having an essentially normal brownish color, the ently infiltrated and of a light color—interstitial bronchopneumonia. Cultures from this lung yielded *Streptococcus hemolyticus* and Friedländer's bacillus. The same organisms were found in other lungs not showing this condition.

In one necropsy with lobar pneumonia in the right upper lobe and lobular pneumonia elsewhere in the lungs, pressure on the lung substance at various places expressed a small drop of thick, creamy pus from the cut bronchioles. This was the only instance in which this condition was seen, although there were five cases in which purulent material was found in the larger bronchi.

In one instance, cross-section of a portion of lung with marked hemorrhagic pneumonitis, the structure was slightly honeycombed with small bubbles resembling somewhat the liver in experimental gas bacillus infections in animals.

Emphysema of most of or at least some part of the air-containing portions of the lungs was always present. Sometimes the distention of the air vesicles was very marked. Interstitial emphysema was very rare. In three instances there were small bubbles of air or gas in the mediastinal tissue, a condition sometimes seen in any necropsy, and apparently in no wise associated with influenza. In two instances there was an apparent escape of air beneath the pleura, raising it up in a few places. By direct pressure these "bubbles" beneath the pleura could be pushed from one part of the lung surface to another. In a number of cases there appeared to be air-containing lines in or beneath the pleura, more or less roughly outlining the lung lobules. These were interpreted as small, once distended but now empty vessels. Aside from these few scarcely noticeable instances of interstitial emphysema, such a condition was not seen. Extensive accumulations of gas beneath the tissues anywhere, such as has been reported by some observers in other localities, was not seen.

No lung abscesses were found. In many cases, had the patient lived, abscesses would have in all probability formed; but in only one instance was there any indication of a distinct softening of any of the consolidated portions of the lungs, and that particular area was solitary and of small size.

Weight of Lungs.—The lungs were usually much increased in weight, owing to pneumonic and hemorrhagic processes or both. The average weight of both lungs together, including a few millimeters of trachea, was 1,953 gm., with extremes of 775 and 3,290 gm. In case each lung was removed separately, a portion of the trachea was always left attached to one. The unusually light pair of lungs came from a very slightly built individual who had a marked lateral curvature of the spine and an unusually small thoracic cavity, and in whom only the left lower lobe was extensively involved in the hemorrhagic pneumonitis. In the case of the pair with the maximum weight, the right lung was very much enlarged and almost uniformly solid; its weight by itself was 2,740 gm. In about half the necropsies, the lungs were removed attached to each other and used as museum objects. In the half in which they were removed and weighed separately, the average weight of the left lung was 870 gm. with extremes of 550 and 1,320 gm. The minimum occurred in the left lung of the pair that weighed the most. The maximum weight of left lung occurred in one having a distinct lobular pneumonic process in addition to the hemorrhagic pneumonitis. The average weight of the right lung was 1,118 gm., with extremes of 650 and 1,560 gm. The lightest right lung occurred in the first case of influenza coming to necropsy, and showed a hemorrhagic process in the upper and lower lobes but not in the middle. The lung was not weighed until after it had been sectioned and lost much blood. The heaviest right lung showed large areas of lobular consolidation and an extensive hemorrhagic process involving all the lobes. The pair of lungs in this instance was the second heaviest pair, being 2,980 gm. in weight. After these two lungs had been cut apart and each was weighed separately, the combined weight of both lungs was then only 2,880 gm., 100 gm. of red, frothy fluid having dripped from the bronchi and trachea. This loss of weight by draining of fluid from the lungs after they were cut apart or sectioned was always considerable, but it was recorded in only a few instances. In one case as much as 400 gm. were lost.

Trachea and Larger Bronchi.—On cutting across the trachea or the main bronchi in essentially all cases, a large amount of reddish or pinkish frothy fluid dripped out; in some cases the fluid was so abundant that the trachea resembled a large blood vessel when cut across. In five cases the fluid dripping from the trachea or bronchi was purulent, and in one case it was mucopurulent. The mucous membrane of the trachea and bronchi was nearly always markedly hyperemic and appeared swollen and deep red, this color being most marked in the intercartilaginous portions. In one case the mucosa was of nearly a normal pinkish gray, but marked with some hemorrhagic spots. Occasionally in some with a hyperemic mucosa there were hemorrhagic spots.

Bronchial Lymph Nodes.—The bronchial lymph nodes were in most cases (thirty-five) enlarged and swollen to a greater or less degree. In a few cases the enlargement was considerable and the nodes soft and edematous, attaining dimensions of from 25 to 30 mm. In five cases the glands are recorded as not enlarged. In the remaining cases they attracted no notice, and were probably normal in appearance.

Hemorrhagic Pleuritis.—One of the more or less striking, essentially constant gross lesions of influenza was what may be termed hemorrhagic pleuritis. By this is meant a bright or dull red spotting seen through the pleura on the surface of the lung. It appeared to be an extravasation of blood beneath the pleura, or else an extensive and local dilatation of the vessels of the surface of the lungs. These spots varied in size from those of a pin point up to spots of 5 or 6 or 10 mm. in diameter. They were irregular in shape, but in general round. The spots were usually more or less grouped together, and were frequently fused into large, hemorrhagic areas of several centimeters in diameter and of a very irregular shape. This subpleural hemorrhagic spotting might be found on any part of the lung. They were less commonly seen on the upper lobes. Sometimes they were much scattered and few in number, so that they were seen only on close examination. Frequently they were present in large numbers on the diaphragmatic surface of the lungs. They were about as common on the interlobular surfaces of the lungs as on the external surface. The interlobular spotting was more abundant, as a rule, toward the root of the lung than toward the periphery. When fibrinous deposits were on the tous changes in the liver, an acute bronchial lymphadenitis, and a moderate dilatation of the right heart.

Secondarily a variety of other lesions developed, such as lobar and lobular types of pneumonia. The lobar types of pneumonia are not typical of the primary form of that disease. A moderate serous pericarditis may develop; very rarely a serofibrinous pericarditis may arise. The pleuritis may become markedly fibrinous. A true empyema may ensue as the result of the usual exciting organisms, but is uncommon. The secondary changes in the lungs appear to be due to various organisms of greater or lesser virulence which happen to be in the respiratory tract at the time of the original attack.

TRANSDUODENAL LAVAGE IN THE TREATMENT OF POSTOPERATIVE ILEUS

AND OTHER SURGICAL AND OBSTETRIC COMPLICATIONS

MAX ERNEST JUTTE, M.D.
Lecturer in Gastro-Enterology, and Assistant Visiting Physician, New York Polyclinic Medical School and Hospital
NEW YORK

A fatal issue in severe complications after laparotomy is so common that the introduction into surgery of a life-saving method in the treatment of these will be welcome. This report concerns six cases of postoperative ileus, a case of incessant hiccup, and also one of puerperal eclampsia, which were successfully treated by transduodenal lavage; every life was saved.

For those unfamiliar with this method, a few words of explanation will be necessary.

Transduodenal lavage flushes the bowel from pylorus to rectum and brings about powerful stimulation of peristalsis. This is accomplished by inserting a duodenal tube just beyond the pyloric muscle, and allowing a sufficient quantity of fluid to run through the tube into the bowel to produce a thorough flushing. The fluid must be slightly hypertonic, so as to remain unabsorbed in its passage along the intestinal tract.

At the New York Polyclinic Hospital, results were observed from transduodenal lavage in medical cases which led to its employment, there and elsewhere, in six cases of postoperative ileus, of which Case 1, the first, is typical:

Case 1.—A woman, aged 50, had had a severe gynecologic operation. Fecal vomiting set in and continued, although everything was done to counteract the condition. The outcome was no longer in doubt; death was certain. As a last resort, transduodenal lavage was suggested and given a trial. No difficulty was experienced in introducing a Jutte duodenal tube, which comes provided with an obturator. The fecal contents of the stomach were then diluted with warm water and siphoned out with the aspirating apparatus which is part of the outfit, and the tube then slipped at once into the duodenum, as shown by the test mentioned in previous papers. The rest of the technic was the same as usual,[1] except that for the purpose of stimulating intestinal peristalsis, the temperature of the irrigating solution was made higher than usual (from 110 to 115 F.). In fifteen minutes there was a precipitous evacuation followed by others.

In the foregoing case and in each of the subsequent cases, only one lavage was necessary, for as soon as normal peristalsis had been reestablished, it continued without interruption. All six patients made an uneventful recovery.

Another striking case is one of incessant hiccup:

Case 2.—A man, aged about 40, who had been operated on at the Presbyterian Hospital for perforated ulcer of the stomach, two days later began to hiccup incessantly, and continued to do so for ten days. Here, too, everything known had been done, but without beneficial results. The patient was doomed. The hiccup was stopped by one treatment of transduodenal lavage, and the man is alive and has not hiccuped since.

In explaining these results, it seems reasonable to attribute them to the stopping of reversed peristalsis and the reestablishment of normal peristalsis, the probable cause of the fecal vomiting and of the hiccup being reversed peristalsis brought about by the operation.

A case of postpartum eclampsia, successfully treated by transduodenal lavage, is no less remarkable:

Case 3.—A woman residing at Newburgh, N. Y., after a protracted period of vomiting during pregnancy, and after parturition, had suppression of urine and became completely edematous. She was in extreme prostration and had been in coma for twenty-four hours. Dr. Bernard Levinson of that city was called in consultation and administered a transduodenal lavage, which was followed in eighteen hours by another lavage. Shortly after that the urine began to flow freely and the patient rapidly regained consciousness; she is now alive and well. This case illustrates well the stimulating effect of transduodenal lavage.

Toxemia of pregnancy offers a promising field for the employment of transduodenal lavage. A few years ago, McDonald[2] reported twelve such cases, which were successfully treated by one lavage each.

I take this opportunity to say that since my first announcement[3] of this new method, which I named transduodenal lavage, several papers have been written by others, dealing with transduodenal lavage, but under slightly different names. The terms which the writers used have been inapt and misleading; the ingredients employed in my solution have been replaced by others, different in name but identical in action.[4]

124 West Fifty-Fifth Street.

Treatment of Functional Paralyses.—Functional paralysis and contractures of all kinds are psychogenic and due to an "idea" generally arising in a psychogenic individual. The idea of the disability tends to become fixed and firmly installed in the minds by daily massage and electricity, especially when carried out by sympathetic women. These cases can be cured by faradism and persuasion in two or three sittings. The cases should afterward be treated by appropriate exercises.—Lieut.-Col. F. W. Mott, Preface to Gymnastic Treatment for Joint and Muscle Disabilities.

SUBCUTANEOUS EMPHYSEMA

WITH THE REPORT OF SEVERAL CASES, PARTICULARLY ONE WITH VERY EXTENSIVE GENERALIZED EMPHYSEMA *

M. E. ALEXANDER, M.D.
Resident Physician, Waterbury Hospital
WATERBURY, CONN.
AND
E. C. FOLLETT, M.D.
Instructor in Pathology and Bacteriology, Bowdoin Medical School
BRUNSWICK, MAINE

Subcutaneous emphysema is referred to in medical literature under various other names, as for instance, surgical emphysema, cellular emphysema and traumatic emphysema. Subcutaneous emphysema may be defined as a condition in which atmospheric air or other gases are found in the subcutaneous tissues. We are concerned here only with the simple emphysema. The inflammatory or gangrenous emphysema is not included.

The subcutaneous tissues are made up largely of areolar connective tissue, which thus permits of a great deal of distention. In either localized edema or in anasarca the accumulated fluids are in these areolar spaces. Similarly in subcutaneous emphysema the entrance of air into these spaces meets very little resistance, and thus the skin becomes distended to a variable extent. In the article on areolar tissue in Garrish's textbook of anatomy,[1] there is a striking picture, a drawing of a man with generalized subcutaneous emphysema. Besides being present in the subcutaneous tissues, areolar connective tissue is also found abundantly in the cellular tissues surrounding muscles, vessels and viscera. Hence emphysema may also occur in and about the various internal organs. There is a case on record[2] of an extensive emphysema of the internal organs, found in a child after having lived ten years with general emphysema.

ETIOLOGY AND CLASSIFICATION

Congenital Emphysema.—This is a very rare occurrence. Nevertheless, there are a few cases on record.[3] This is either a result of rupture of a few pulmonary vesicles in the act of the first cry, or a result of some congenital malformation of the respiratory passages with the result of an inrush of air into the subcutaneous tissues with the first breath.

Emphysema in Infants.—Rupture of some pulmonary vesicles with the result of subcutaneous emphysema has been observed by various authors.[4] It is generally considered that some congenital weakness of the lung preexisted in these cases. A violent exertion or coughing fit causes a rupture of some pulmonary vesicles, and permits the escape of air into the interlobular or interlobar spaces. From here the air passes along the root of the lung, through the anterior mediastinum to the root of the neck, and may thence spread to the chest and the arms, or all over the body.

Traumatic Emphysema.—*A.* Of External Origin: Various wounds, such as stab wounds produced by a lance or bayonet, may result in an inrush of air into the wound producing emphysema of variable extent. Many such cases have been reported. Some of them have become classical and are frequently cited, such as the case described by Larrey.[5]

Puncture wounds, even such as those produced by an ordinary medium-sized exploratory needle, have been known to produce emphysema, even of a very extensive variety. Evans[6] reports a case of generalized emphysema following an exploratory aspiration of the chest. We have encountered a case of extensive emphysema following the insertion of trochar and cannula for the introduction of a catheter in the treatment of empyema with irrigation of neutral solution of chlorinated soda (Dakin's solution).

Case 1.—A woman, aged 24, with empyema of the right side of the chest, when a trocar and a cannula had been inserted and the trocar had been withdrawn, in order to allow the pus to run out through the cannula, turned unexpectedly, which caused the cannula to slip out of the pleural cavity. Suddenly the patient became quite dyspneic and complained of a distressing sensation of tightness and oppression in the chest. The trocar had become unsterile, and we had to wait for its resterilization. In the meantime, firm pressure was applied to the puncture wound. When the cannula was reinserted the distressing symptoms all disappeared, but distinct subcutaneous crepitus was soon observed extending to the floor of the mouth above, and down to the abdomen below. The air gave rise to no disturbance, was all absorbed at the end of two weeks, and the patient made an uneventful recovery.

In many of these cases it is hard to decide whether the emphysema is of external origin or of internal origin due to an injury to the lung. For instance, there is a case[7] on record of a soldier sustaining a bayonet wound of the buttock, with the development of an extensive emphysema soon afterward. It is difficult to see how a wound in that region could injure any air-containing viscera. Col. Nathan Raw, however, has, in connection with this case, demonstrated on the cadaver that a knife 8½ inches long could be pushed up from the buttock behind the peritoneum along the muscles of the back, pierce the diaphragm and injure the lungs.

B. Of Internal Origin: 1. Gastro-intestinal. Subcutaneous emphysema has been described as a result of the rupture of almost any part of the alimentary canal, as for example the esophagus, the stomach or the rectum.

Pierce[8] describes a case of generalized emphysema in a drunkard that gave neither evidence nor history of any external traumatism. At necropsy there was found an ulcer of esophagus with a sinus leading to an abscess of the stomach situated near the cardiac end. The ulcer had ruptured, with the escape of food into the mediastinum and air into the subcutaneous tissues.

A case of general emphysema following rupture of the stomach is described by Newman.[9] This occurred in an insane patient. At necropsy the lungs and pleurae were found normal. The peritoneal cavity was extremely distended with air, and the stomach was ruptured.

Erichsen[10] reports a case of perineal emphysema spreading to the upper parts of the body from puncture of the bladder through the rectum, for retention.

2. Air Passages: What is true of the alimentary canal is true of the air passages. The rupture of almost any part may produce the emphysema, for example, the nose and accessory sinuses, the larynx, trachea and bronchi, or the lungs. Compound fracture of the nose has been known to produce quite extensive emphysema. It most frequently follows an attempt to blow in order to dislodge an annoying blood clot. Similarly, emphysema has been known to follow injuries to the accessory sinuses, especially the frontal sinus. The earliest case of this kind on record is probably the one reported by Morgan:[11]

> These cases are evidently not very rare. We have encountered three such cases within the last three years. One of them presented an emphysema extending down to his abdomen. Necropsy showed a fracture of the frontal bone through the frontal sinus.

Subcutaneous emphysema may also follow injury to the antrum of Highmore and to the mastoid process.[12]

Attempts at inflating the middle ear not infrequently produce a submucous emphysema of variable extent. Instead of entering the eustachian canal, the tip of the instrument is forced under the mucous membrane, and in the process of inflation air is forced into the submucous tissues much to the patient's alarm. In some cases the emphysema thus produced may be quite extensive, and has been known[13] to reach the root of the neck.

Emphysema may be caused by tuberculosis and malignancy of the larynx,[12] or by wounds of the trachea. A tracheotomy may give rise to very extensive emphysema if the external opening is too small.[14] Erosions following foreign bodies in the bronchi have been known to produce emphysema, such as in a case reported by Whelchel.[15].

Wounds of the lungs quite frequently occasion emphysema.[16] The overlying skin may or may not be affected. It is also very commonly associated with, or rather a result of, fracture of one or more ribs. Localized emphysema is very common in connection with these accidents. They are frequently overlooked. As a rule, these cases are associated with very extensive injuries, such as result from being run over, falling down stairs, etc. The mechanism of the phenomenon is simple. The point of the fractured rib injures the costal pleura, visceral pleura and lung tissue, but not the overlying skin. During inspiration the lung expands and air rushes into the pleural cavity through the laceration. During expiration the lung collapses; the laceration becomes closed, so that the expiratory effort can not drive the inspired air back through the same opening, but drives it into the distensible subcutaneous tissues instead.

Emphysema of the Tissues Surrounding an Abdominal Wound After Laparotomy.—This is a rather curious manifestation, yet on reflection one need not marvel over its occurrence. During the operation air enters the peritoneal cavity, and we may readily assume that at times quite an amount may remain in the cavity after the peritoneum is sutured up. Under normal conditions the enclosed air becomes absorbed very readily. Occasionally, however, it may remain for a long time, and should the patient strain or cough, the enclosed air may find its way through the sutured peritoneum and into the subcutaneous structures.

Case 2.—A man, aged 25, had appendectomy performed, in January, 1917. It was an interval operation, and it seemed perfectly safe to close the abdomen without drainage, which was done. Two days after the operation the patient developed a distressing cough. The temperature was 101.4 F., pulse 110, respiration 28. Next day the patient's temperature rose to 102, and he also complained of a discomfort about the incision. The wound was dressed, January 28, the fourth day after the operation. There were no signs of inflammation, but gaseous crepitus was distinctly felt around the wound and extended for a distance of 4 inches to each side. The patient's temperature was without a doubt due to bronchitis. The air was all absorbed at the end of fourteen days, and the patient made an uneventful recovery.

Similar cases have been recorded from time to time. Von Graefe[17] reported two such cases in 1894. Von Caspersohn[18] reported one in 1895. The air, in his case, showed no tendency to be absorbed, and incision was made on the twentieth day after operation. Von Heil[19] reported one case in 1896 and another in 1900. Madlener[20] has written a comprehensive article on this subject, and estimated the number of cases reported to be above twenty-five.

Spontaneous Emphysema.—By this term is meant the occurrence of emphysema after extensive subcutaneous extravasation of blood. This subject has been widely disputed, and many doubt the possibility of its occurrence. Nevertheless, many authorities attest to its possibility. Valpeau described it as occurring not infrequently in connection with fractures, particularly of the shoulder.[21] According to H. Fischer,[22] the emphysema appearing in these extensive hematomas is due to gases produced by the action of acids, such as lactic acid, on the contained blood. He demonstrated these acids in contused tissues, and has also produced emphysema experimentally by injecting lactic acid into hematomas experimentally produced in animals. In one such experiment these gases were demonstrated to be carbon dioxid.

Emphysema During Labor.—This is not encountered very frequently; nevertheless there are a number of cases on record, some of them very extensive in nature. It usually occurs in the second stage of labor. during the period of expulsion. Owing to excessive straining some pulmonary vesicles rupture, and emphysema results. It becomes manifested first at the root of the neck. Judging from the remarks made by the authors that have reported cases, the condition is not seen very commonly, most of them not having encountered a similar case before. Some of the more recently reported cases are by Milne,[23] Murray,[24] and Fabre and Trillat.[25] Scheffelaar Klots[26] has written a comprehensive article on this subject and has collected forty cases from the literature.

[16] Since this paper was written, Clark and Synnott (Am. J. M. Sc. **158**: 219-221 (Feb.) 1919) have reported twenty cases of subcutaneous emphysema observed in connection with influenzal pneumonia during the epidemic at Camp Dix. The "gas" first made its appearance in the subcutaneous tissues at the base of the neck "anteriorly and laterally and over the upper portion of the chest from the clavicle to about the third rib." In one of the cases the emphysema extended to the chetks, eyelids, arm, abdomen and flanks. From postmortem investigations made in three of the cases, the origin of the gas was from "weakened alveoli of the lung under pressure, . . . and reached its distribution as a result of purely mechanical factors."

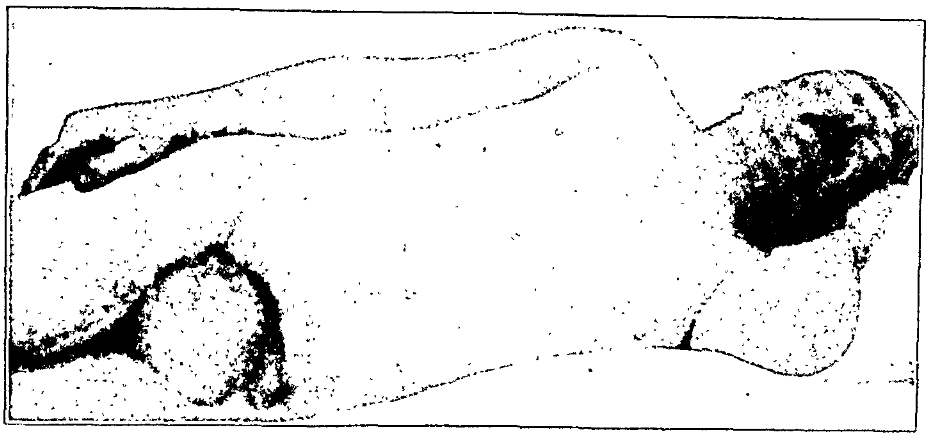
Generalized Emphysema.—In reviewing the literature, one finds reports of a considerable number of cases of generalized emphysema. Nevertheless, one may conclude that it is not very common, as is evidenced by the remarks of a great many of the observers that it is the only case of the kind they have ever seen. When well developed, the condition is so striking and so impressive that it may be safely assumed that the cases in the literature are the records of perhaps the greatest percentage of the cases observed. We may, therefore, be justified in reporting the following case in detail:

Case 3.—*History.*—J. S., a farm hand, aged 69, with a negative past history, fell down five steps, Jan. 1, 1918, and struck the right knee and the side of the chest. He complained of sharp pain in the chest, but with slight help he was able to walk outdoors and for some distance toward the barn. Very soon, however, he felt worse and was carried upstairs and put to bed. About two hours later he noticed that he was beginning to be puffed up, and by morning he found that his eyes were so swollen that he was unable to open them. Dr. Robbins was called in and advised removal to the hospital. The patient was admitted to the Waterbury Hospital, January 2, at 2 p. m.



Generalized emphysema: condition day after admission to the hospital.

Examination.—On admission the patient was found to be markedly dyspneic and universally bloated, presenting a condition not unlike that of extreme anasarca from Bright's disease. His temperature on admission was 99 F., pulse 94, respiration 24. On physical examination this generalized swelling was found to be an emphysema involving the entire body, with the exception of the scalp, palms of the hands and soles of the feet. The eyes were so puffed up that no effort availed to open them. The lips were extremely swollen, making articulation and even opening of the mouth very difficult. The voice was very high-pitched and cackling in character, not unlike that of a hen. The penis was extremely swollen and distorted, and the patient had been unable to void for ten hours prior to admission. The scrotum was as large as a good-sized grapefruit, and the abdomen gave the impression of extreme ascites.

On palpation the characteristic crackling crepitus could be felt all over the body except the scalp, the palms of the hands and the soles of the feet. Bony crepitus could be felt over the lower ribs on the right side, but it was impossible exactly to determine which ones were involved. The apex beat could not be felt. On auscultation over the site of fracture a shrill, high-pitched sound could be heard, inspiratory in time, and a distinct, loud, jarring noise during expiration. Both sounds were accompanied by numerous crackling crepitations evidently right under the stethoscope. The heart sounds were distant and hard to elicit. The neck was 19 inches in circumference, the forehead, 23 inches, the chest at the level of the axillae, 43 inches, and at the level of the nipples, 38½ inches, and the middle of the arm, 15 inches. It is probably useless to cite all the other measurements taken. The condition of the patient is shown in the accompanying figure.

Subsequent Course and Treatment.—The patient was quite dyspneic, rather cyanosed, coughed a great deal, and expectorated some tenacious sputum tinged with blood. The patient's chest was strapped tightly with adhesive straps and one-fourth grain of morphin given hypodermically, and one-sixth grain of morphin was left to be given rather freely as circumstances required. The patient was somewhat more comfortable after the morphin and strapping, but was still in considerable distress the first night. Next morning, however, he felt much better. The emphysema had not increased, and the pain in the chest was much less. The dyspnea was less urgent, although swallowing was still difficult. In view of the slight improvement, we decided to leave the patient alone and to make no punctures to serve as outlet. For the next two days the patient's condition remained about the same; but afterward rapid improvement was noticed, and by the end of the week the patient's condition seemed to be exceedingly good; in fact, he seemed to be out of danger.

Fluoroscopic and roentgenographic examinations made six hours after the strapping of the chest showed the fractured ribs to be in good position.

Physical examination of the chest at the end of the first week was still rather difficult because of the interference of the superficial layer of air; nevertheless, the affected side was distinctly tympanitic to percussion as compared with the opposite side. On auscultation the breath sounds were feeble and distant as compared with the exaggerated breath sounds on the opposite side. Metallic tinkling and the coin sound, or the *bruit d'airain* of Trousseau, were distinctly heard. The patient evidently had a pneumothorax. Succussion sounds were negative.

Examination of the urine, blood and sputum disclosed nothing of special interest.

The patient continued to make an uneventful recovery. By the end of ten days practically all the air had disappeared except in the arms and scrotum, where it could still be detected for another week, at which time it had entirely disappeared. He was a fairly well developed man, thin in face and neck and otherwise without much subcutaneous fat. He was discharged, January 30, cured.

ANATOMIC EXTENT OF SUBCUTANEOUS EMPHYSEMA

The exact distribution of the emphysema varies in different cases. It depends on the extent of adherence of the skin to the subjacent structures. The scalp, the palms of the hands and the soles of the feet are very seldom involved. I could find no mention in the literature of any cases in which the emphysema extended to these parts of the body. In some cases, because of scars or adhesions from other causes, certain parts that are usually affected may escape, as was

true in a case reported by Buchanan,[27] in which, though the chest, abdomen and face were extremely swollen, the eyes escaped entirely. The part over the patella frequently escapes, but in the case just reported there was as much air over the patella as over the rest of the limb.

INDUCED SUBCUTANEOUS EMPHYSEMA

In 1885, Silvester[28] published an article advocating the employment of induction of emphysema as a life-saving device. He demonstrated that if a dog "be blown up" he will support and prevent from drowning one or more human beings. Before the Royal Academy of Science he introduced a cannula into an individual's wrist and induced a generalized emphysema with the aid of a small pump. For the self-induction of emphysema he advocated a still "simpler" device. When one is in peril from drowning one may puncture, with any sharp instrument, the floor of the mouth near the base of the gums. With the finger of the other hand as a guide, the tissues are penetrated till the superficial fascia of the neck is reached. The mouth and nostrils are closed, and with each expiratory effort air enters the subcutaneous tissues and extensive emphysema may thus be produced, enough, according to the author, for the individual to float an indefinite length of time. This measure has evidently never been received with enthusiasm, not even during war time.

Complications of Subcutaneous Emphysema.—These are (*a*) extension to the mediastinum; (*b*) extension to the internal organs; (*c*) hemopneumothorax and pyopneumothorax, and (*d*) erysipelas and cellulitis.

PROGNOSIS

Generally speaking, prognosis is good; but it depends on the origin and the complications. The extent of the emphysema seems to play only a small part. The emphysema brought about by the rupture of the stomach or intestine is uniformly fatal. The emphysema resulting from injury to the lung generally has a good prognosis except for the complications. Extension of the emphysema to the mediastinum is uniformly fatal. We found in the literature twenty cases of generalized emphysema produced by fracture of ribs, with no external openings; of these, three cases ended fatally (15 per cent.). Death in two of these cases resulted from collapse of the lung and hemopneumothorax, and one patient died from extension of the air into the mediastinum. Absorption of the air in emphysema generally takes place in from one to three weeks.

TREATMENT

That the slight and limited subcutaneous emphysema requires no special treatment and no operative procedure is universally accepted. About the extensive and generalized emphysema, the opinions differ. In consulting some of the old authors on surgery, we find that they also disagreed about the procedure in these cases. Abernethy,[29] for instance, was of the opinion that these patients do best when left alone. In two cases in which he operated death ensued. He also recommended the firm bandaging of the chest with towels or adhesive plaster:

> In whatever state the lungs happen to be when they are wounded, a bandage, if it can be borne, seems to me extremely useful. By means of it the pain and irritation which the motion of the fractured ribs must otherwise occasion are in a great measure or entirely prevented.[30]

Samuel Cooper,[31] on the other hand, recommends multiple incisions and condemns the use of bandages. Larrey[5] also recommends multiple incisions.

Of the more modern authors, Bryant[32] and Lucas[33] both recommend multiple punctures. Von Bramann[34] advocates the insertion into the pleura of a tube provided with a valve which prevents the escape of air into the tissues. Lexer[35] is in favor of bold surgical procedure. He advises the stopping of the exit of air by means of tamponing, suturing the pleura or the insertion of the Bramann tube just mentioned. Keen,[36] on the other hand, advises leaving it alone unless the distress is extreme, when multiple punctures are advocated. Vaughan[37] says that emphysema "requires no treatment unless excessive, when multiple punctures in the skin and the application of bandages to the chest may be necessary."

From a review of the modern literature the general opinion seems to be that subcutaneous emphysema generally requires no special treatment beyond that of the condition causing it. It does not materially influence the prognosis, except when the emphysema extends to the mediastinum and internal organs. In emphysema ocurring during labor, the patient should be instructed to be very quiet and not to strain, and the child would best be delivered with forceps. In all cases of emphysema, coughing and straining should be allayed by the aid of morphin. Strapping of the chest should be tried, but should be abandoned if the pain and discomfort are aggravated thereby. Punctures and incisions are generally unnecessary. and should be made only in extreme cases.

Mosquito Eradication.—The report of the Atlantic County Mosquito Extermination Commission for 1918 shows that during 1918 there were constructed 407,839 feet of ditches, and that since 1913, when the work began, 5,866,514 feet of ditch have been made. This has resulted in a decided improvement in the mosquito situation in Atlantic City and the surrounding resorts and towns throughout the county, though it is a constant fight to keep what has been gained by the preventive operations. Mosquitoes of the salt marsh variety, as well as the common house mosquito, must be constantly fought; and it is a matter of persistent vigilance to prevent the breeding of the pests in every hole or receptacle that will hold even a small quantity of water. Citizens do not always cooperate as they should about their places. During 1918, Atlantic City was free from mosquitoes except on two nights, and the surrounding resorts had almost as good a record. During the year, 1,124 acres of salt marsh were drained, and previously 18,756 acres had been drained. The total area drained constitutes about 30 per cent. of the area requiring drainage. The expenditures for 1918 were about $23.000.

MAGNESIUM AND CANCER *

SHIGEMITSU ITAMI, M.D.
NEW YORK

There has appeared recently an article by Dubard,[1] wherein the author suggests the administration of magnesium salts to cancer patients who have undergone operation, in order to lessen the chances of recurrence. The same agent had been used some twenty years before by Gaucher and Herscher,[2] who reported favorable results after the application of a paste of magnesium chlorid to an ulcerated epithelioma of the lower lip. Regnault,[3] also, was encouraged by the outcome following the internal administration of magnesium salts in cases of inoperable cancer, and has accordingly been using them systematically in the hope of avoiding recurrence.

It is fortunate that experimental cancer research permits such suggestions as these to be examined in the laboratory, for the clinician's obligation to save human lives imposes on his investigations a restriction that does not hamper the experimental pathologist.

A laboratory devoted to cancer research, again, can command various types of tumor, such as a transplantable mouse carcinoma (Bashford's 63), which grows progressively, another carcinoma (Bashford's 206), which often recedes after growing for two or three weeks, a number of spontaneous mouse carcinomas, etc.

Of these three types, the two transplantable carcinomas should yield more easily to therapeutic attack than the spontaneous growths, since the former consist of mouse cells growing in mice other than those in which they first became cancerous; hence it may be assumed that they are proliferating under conditions less favorable than those surrounding a spontaneous neoplasm, whose cells are those of the very mouse to which they are native. And of the two transplantable growths, 206 should be more easily influenced by treatment, since its cells are so delicately balanced that this tumor often regresses without any treatment whatsoever.

Yet the intravenous injection of magnesium chlorid in doses of from 0.003 to 0.007 gm., an amount which is relatively five or eight times larger than the toxic dose for man (3 to 4.5 gm.), was without effect on these two mouse tumors, even when two or three treatments were given within a few days (Fig. 1). This was also the case when medication was begun within twenty-four hours after introduction of the tumor graft—that is, before it had become vascularized and at a time when it was therefore most vulnerable (Fig. 2). Spontaneous neoplasms, also, pursued their course quite uninfluenced by the treatment (Fig 3). The arrows show the time when magnesium was injected.

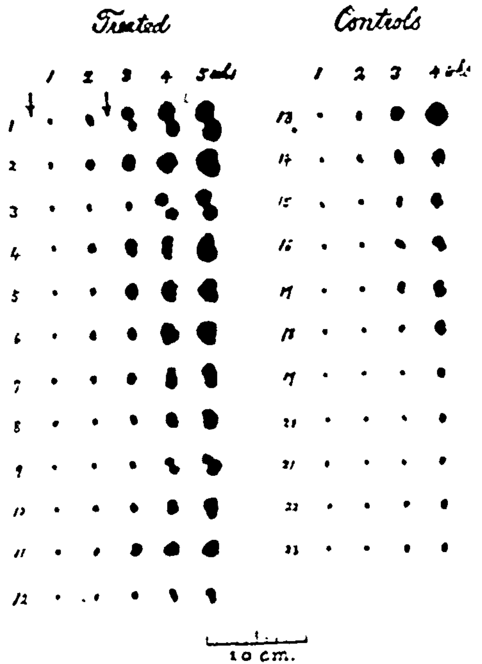

Fig. 1.—Mice 1 to 12, bearing Carcinoma 63, were treated twice with magnesium—five and sixteen days after the tumor was inoculated. Mice 13 to 23 were normal untreated controls. At the end of the fourth week the tumors in the treated animals were larger than those in the controls.

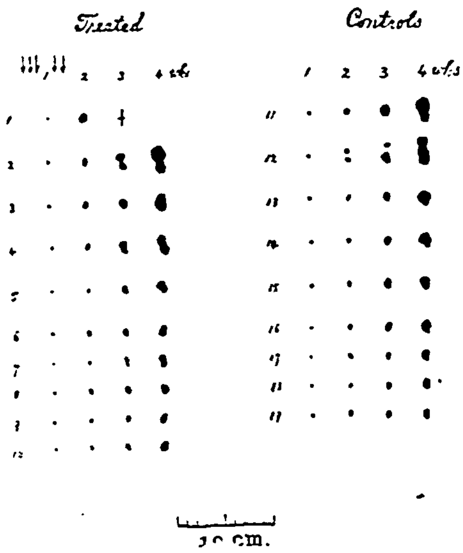

Fig. 2.—Mice 1 to 10, bearing Carcinoma 206, were treated five times with magnesium—two, four, six, eight and ten days after the tumor was inoculated. Mice 11 to 19 were normal untreated controls. The magnesium exerted no effect on the growth of the tumors.

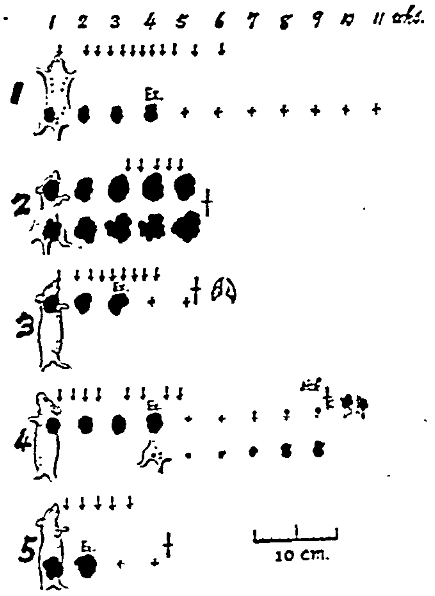

Fig. 3.—Mice 1 to 5, bearing spontaneous carcinomas, were treated from five to eleven times with magnesium, without influence on the growth of their tumors. In Mouse 4, a recurrence appeared within the third week after the last (eighth) treatment; this is shown at the ends of the small vertical which, by convention, represent the operation scar. Furthermore, a new growth was discovered in the right groin, just after the sixth treatment, and at necropsy the lungs were found to be extensively involved by metastases. In Mouse 3, also, the treatment did not prevent the occurrence of metastases in the right lung.

Not only were no tumors cured in 175 animals, of which the three groups here reproduced are a fair sample, but in one mouse which was being injected with a view to preventing, if possible, the recurrence of a spontaneous neoplasm previously extirpated, a secondary growth appeared about three weeks after the eighth injection; furthermore, a new spontaneous tumor arose during the treatment (Mouse 4, Fig. 3). Both the recurrent and the new tumor must have consisted at first of a small group of cells; yet even these growths, which might almost be called incipient, were entirely untouched by magnesium.

Needless to say, all the tumors concerned in the experiment were submitted to microscopic examination, in order that their carcinomatous nature might be proved.

Since carcinomas of the mouse are quite comparable to those in man, arising in animals that have

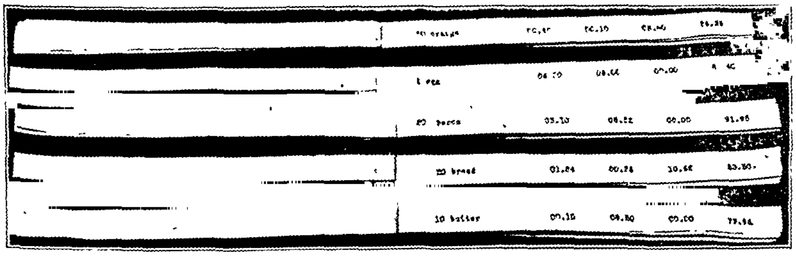
passed middle life, invading the surrounding structures, metastasizing by both blood and lymph channels, and ultimately destroying life, these experiments cast serious doubt on the value of magnesium in the treatment of human neoplasms. In fact, the assertion may be ventured that this element will prove to be useless. It is in order that this knowledge might be gained as quickly as possible and with the sacrifice of animal rather than of human lives, that the experiments described in this paper were undertaken.

Clinical Notes, Suggestions, and New Instruments

A FILING METHOD HELPFUL IN FIGURING CALORIC FOOD VALUES

Rose Donk, M.D., Buffalo

The figuring of diets that shall have certain desired values in protein, fat and carbohydrate is tedious and time consuming. Attempts to overcome this difficulty by the use of approximate values are of most uncertain success. The tables procurable for common measure are incomplete, and their use not only does not save time, but is likely to cause gross error.



Booklets arranged to show values for 50 gm. of orange, 1 egg, 20 gm. of bacon, 20 gm. of bread and 10 gm. of butter. The first column of figures represents the number of grams of protein in each; the second, the number of grams of fat, and the third, of carbohydrate. The fourth column represents the number of calories.

It is necessary to use the metric system. The diet is to be made out according to the number of grams of protein, fat and carbohydrate that are desirable.

The tables of Atwater and Bryant[1] are most convenient as a basis of computation. These tables give the percentage of protein, fat and carbohydrate in various foods. They give the fuel value per pound. The fuel value per hundred grams would be more convenient for the present purpose and it must be figured out. If, in estimating a diet, one refers directly to the tables, one must estimate the caloric value by multiplying the number of grams of protein by 4.1, the number of grams of fat by 9.3, and the number of grams of carbohydrate by 4.1, that is, by the fuel value for a gram of each. For example, 100 gm. of boiled potato (Atwater and Bryant) contain 2.5 gm. of protein, 0.1 gm. of fat and 20.9 gm. of carbohydrate.

The caloric value of 2.5 gm. of protein equals 2.5 multiplied by 4.1, or 10.25 calories.

The caloric value of 0.1 gm. of fat equals 0.1 multiplied by 9.3, or 0.93 calory.

The caloric value of 20.9 gm. of carbohydrate equals 20.9 multiplied by 4.1, or 85.69 calories.

The total number of calories for 100 gm. of potato equals 96.87.

From these values for 100 gm., one then figures the values for whatever amount is to be ordered.

Any system in which these multiplications and additions are already made out is very helpful. Moreover, if the values are figured in multiples, one gets directly the number of grams of protein, fat and carbohydrate and the total fuel value for 10, 20, 30, 40 or more grams of the food, as may be desired.

Ordinary index cards may be used, arranged as shown in the accompanying tabulation.

In using the card system one, of course, copies the values for the various foods in the amounts desired. Additions are then made to get the totals for the day.

INDEX CARD SHOWING THE VALUES FOR ORANGE IN MULTIPLES OF TEN

Gm. Orange	P.	F.	C. H.	Cal.
10	.08	.02	1.16	5.27
20	.16	.04	2.32	10.54
30	.24	.06	3.48	15.81
40	.32	.08	4.64	21.08
50	.40	.10	5.80	26.35
60	.48	.12	6.96	31.62
70	.56	.14	8.12	36.89
80	.64	.16	9.28	42.16
90	.72	.18	10.44	47.43
100	.80	.20	11.60	52.70
110	.88	.22	12.76	57.97
120	.96	.24	13.92	63.24
130	1.04	.26	15.08	68.51

The desire to avoid this copying of figures leads one to search for a device offering this further convenience. The following serves that purpose:

Small, narrow booklets are made, as illustrated herewith. For example, one can open the bacon booklet at 10, 20 or more grams as may be desired. The egg booklet may be opened at one or two eggs. The number of grams of protein, fat and carbohydrate and the caloric value are at hand. No copying is necessary, as the booklets may be placed one below the other, the foods desired for the day being chosen from the stock of booklets. Once the diet is thus arranged, additions are made to find if the totals for the day are satisfactory. If such is not the case, more or less of a given food may be substituted by turning the leaves of the particular booklet to the corrected quantity.

These booklets were made by typing from the original card index system. The tabulating key was useful to keep spacing uniform. A photograph trimmer was used to cut the typewritten sheets into narrow strips. Binding was done by the use of punch and brass eyelets. Adhesive plaster is useful to reinforce the binding.

In actual use in the laboratory, it has been found convenient to hold the booklets in position by the use of thumb tacks stuck through the eyelets, an ordinary kitchen table being used for thus laying out the menu.

The time required for computing diets by this record system is relatively small. It likewise diminishes the chance of arithmetical error.

WATER ABSORBING CAPACITY OF DUSTING POWDERS*

Torald Sollmann, M.D., Cleveland

The value of dusting powders is determined partly by their capacity for absorbing or retaining excessive fluid, for example, from the skin, from open wounds, from the intestine in dysentery, etc.

RELATIVE WATER CAPACITY OF DUSTING POWDERS, ARRANGED IN ORDER OF EFFECTIVENESS

Powder Tested	Weight of Water Held by 3 Gm. of Powder	Retained Water as Per Cent. of the Powder
Starch (corn)	2.39	80
Kaolin	2.19	73
Fullers' earth	2.09	70
Precipitated calcium carbonate	1.94	65
Talcum	1.84	61
Prepared chalk	1.59	53

---

[1] The Chemical Composition of American Food Materials, Bull. 28, U. S. Dept. Agr.

* From the Pharmacological Laboratory of the Western Reserve University School of Medicine.

These uses suggested the desirability of ascertaining the relative water absorbing capacity of these dusting powders. This was done by shaking 3 gm. of the powders with an excess of water, throwing on a filter and permitting to drain quite thoroughly, and then weighing the moist powders. All experiments were made at the same time, so as to make the results comparable. They are shown in the accompanying table.

CONCLUSIONS

The commonly used dusting powders do not differ very materially in their capacity for holding water. However, starch, kaolin and fullers' earth are more effective than chalk or talcum.

NEW ARM BOARD*

Vernon C. David, M.D. (Chicago)
Major, M. C., U. S. Army
Limoges, France

One of the most useful improvisations made in the splint room of U. S. Army Base Hospital 13 was an arm board designed by Private Harold E. Poff, who, prior to his entrance into Base Hospital 13 as a patient, had never been inside of an operating room. This arm board has numerous advantages over an arm board that must be placed under the patient and which has a limited degree of adjustability.

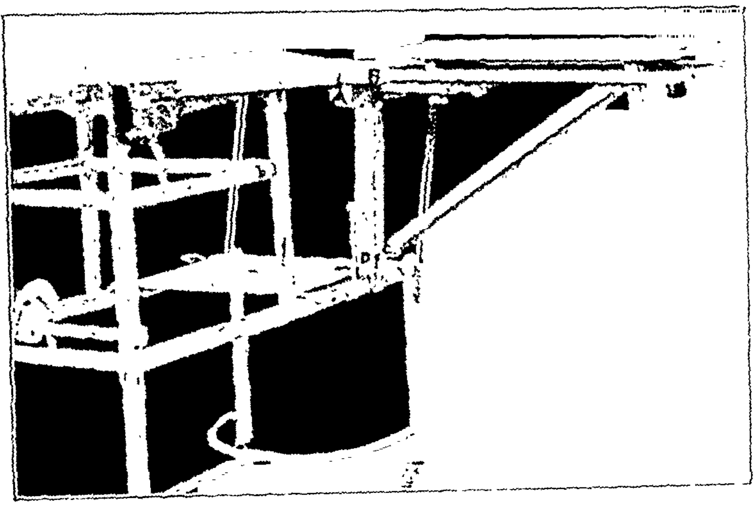


Fig. 1.—Arm board attached to operating table: *A*, groove fitting edge of table; *B*, beveled edge of a fixed semicircular board around which the arm board rotates; *C*, ball and socket joint allowing rotation of support of the arm board; *D*, sliding catch to attach apparatus to operating table.

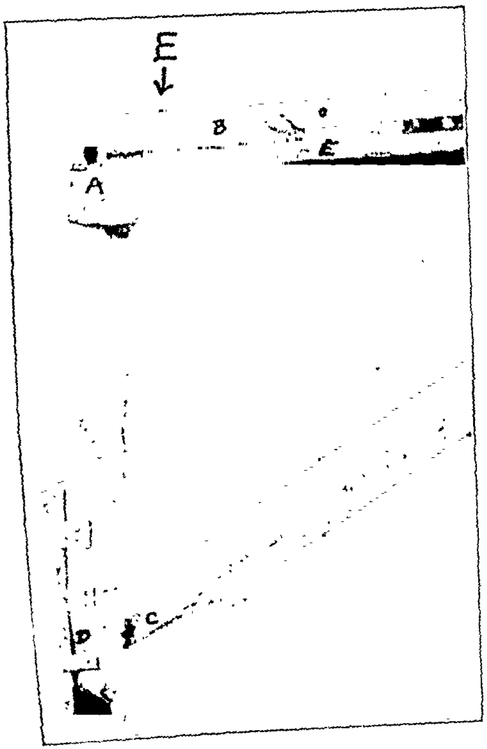

Fig. 2.—Details of arm board.

The accompanying illustrations show the apparatus as made by Private Poff out of such simple materials as were at hand. It is the purpose to submit the design drawn by Private Joseph Conklin to an instrument maker on our return to the United States and have a board made.of aluminum embodying a few improvements which have suggested themselves.

The advantages of this arm board to us have been: (1) its rapid application to or removal from any standard operating room table without moving the patient; (2) a free arc of rotation in the horizontal plane, making the apparatus suitable for either arm and enabling the operator to easily

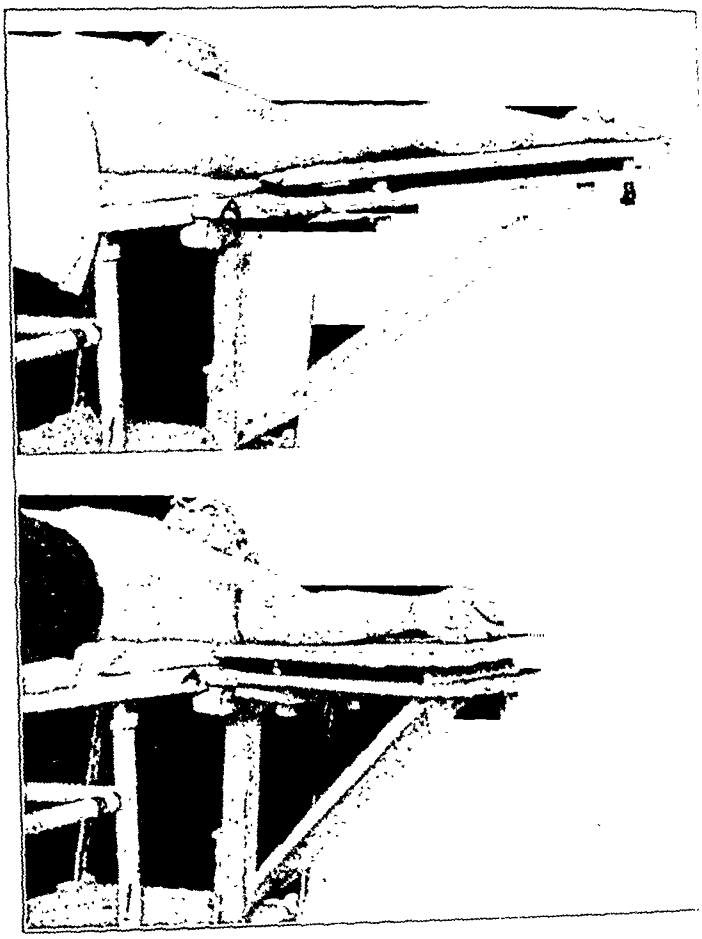

Fig. 3.—Different positions of arm board in a horizontal plane aro the semicircle at *A*.

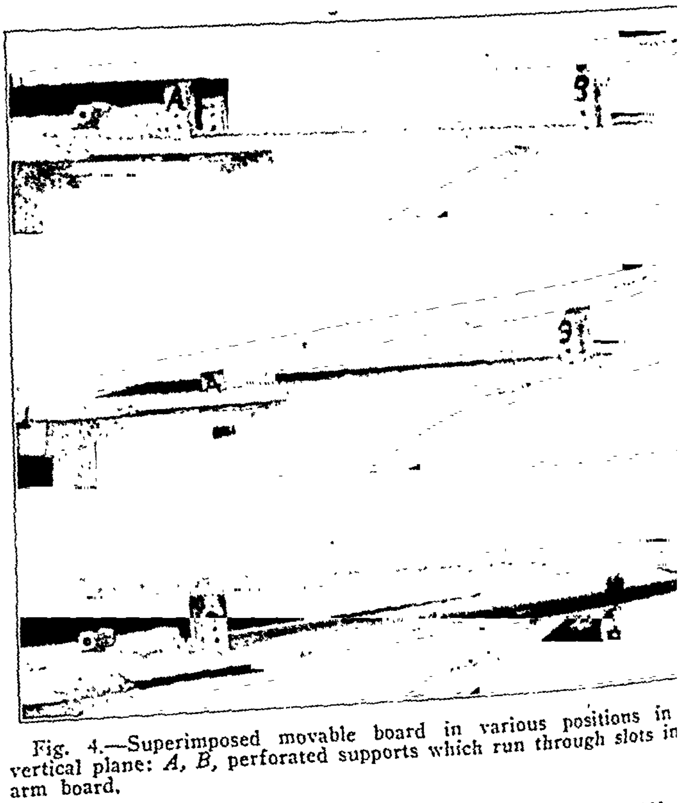

Fig. 4.—Superimposed movable board in various positions in vertical plane: *A*, *B*, perforated supports which run through slots in arm board.

change the degree of abduction of the arm, and (3) adjustability of the arm in the vertical plane, making it sible to change the degree of flexion of the arm.

The arm board is attached to the operating table by m of a groove at each end of an upright. The upper gr (Figs. 1 and 2 *A*) fits under the vertical edge of the t and the lower groove (Figs. 1 and 2 *B*) over the rod run beneath the table, where it is held by a movable catch.

The horizontal rotation of the board is made possible the rotation of the board around a fixed semicircle of w the circumference of which is beveled at the expense o upper surface (Figs. 1 and 2 *B*). The part of the arm board in contact with the semicircle is also beveled at the expense of its under surface. The stationary semicircular piece and the movable arm board are held together at this beveled joint by a small board beneath the arm board, which is attached to the arm board and to a screw in the center of the fixed semicircular piece (Fig. 2 *E*).

---

*From Base Hospital No. 13.

The arm board is supported by a board running from the upright attached to the operating table to the outer end of the arm board. In order to allow rotation of this piece, a ball and socket joint is provided at its junction with the upright attached to the operating table (Figs. 1 and 2 *C*).

To allow a change of position of the patient's arm in the vertical plane, a superimposed board, the same size as the arm board and supported by four legs, is employed. These supports run through slots in the arm board proper; and by means of pegs inserted in holes in the supports, the outer or inner end or both ends of the superimposed board may be raised. This superimposed board may be removed entirely, but we have found it to have definite advantages in obtaining stability of the patient's arm.

The degree of adjustability of the board in the horizontal plane, increasing the abduction or adduction of the arm, is shown in the accompanying illustrations. In the illustrations the foreshortening lessens the apparent degree of rotation, which may be seen by noting the change in the patient's axillary fold.

A CASE OF CONGENITAL MALFORMATION OF THE LEFT FOREARM WITH ABSENCE OF THE HAND

J. J. Kurlander, M.D., Cleveland

B. C., a boy, aged 9 years, is healthy and normal in all respects except for the left upper extremity, which at first sight resembles very closely an intra-uterine amputation through the upper third of the forearm. The humerus is normal in size and function. There is normal range of motion at the elbow. The radius and ulna are palpable, and at their distal end is a small piece of bone, to which is attached a flexor and an extensor tendon. This small bone, evidently a rudimentary metacarpal bone, can be very easily flexed and extended. The stump is well shaped and padded.

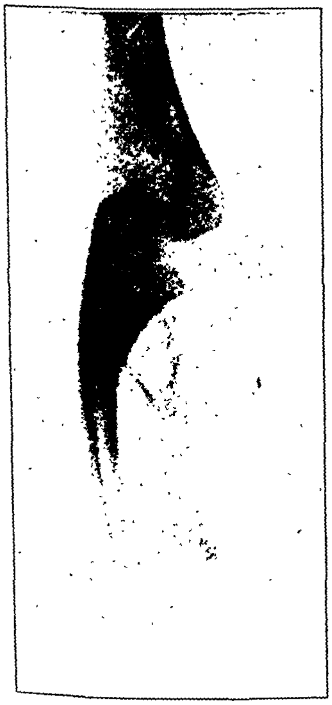

Fig. 1.—Congenital malformation of forearm, lateral view.

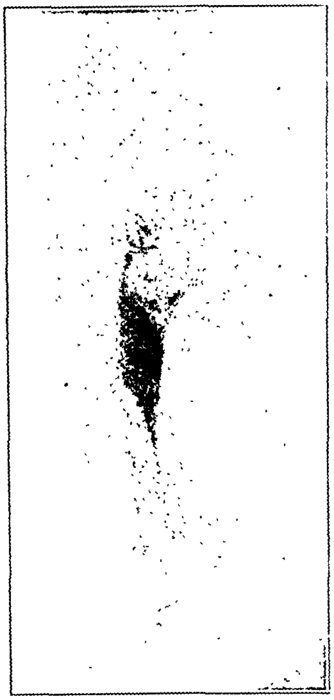

Fig. 2.—Congenital malformation of forearm, anteroposterior view.

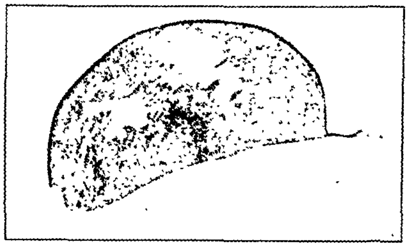
The roengenograms show that the condition is not an intra-uterine amputation, since both the radius and the ulna are practically perfectly formed, being only half or one third the normal length. There is complete absence of carpal and metacarpal bones, with the exception of the single rudimentary metacarpal bone, and absence of phalanges. When the boy becomes older, an artificial arm will be ordered.

630 Osborn Building.

HERNIA OF THE ENTIRE STOMACH, RESULTING FROM STAB WOUNDS, SUCCESSFULLY REDUCED WITH RECOVERY

Carlos C. Booth, M.D., Youngstown, Ohio
Surgeon, Youngstown Hospital

During my recent term of service, I was called at 4 a. m., Oct. 1, 1918, to see J. L., aged 41, a laborer, who had just been brought into the hospital. He had a projecting tumor immediately over the region of the stomach covered only by clothing. On inquiry, I learned that he had been in a drunken brawl the night before, and on his way home had become involved in a fight with his companion, who stabbed him in the region of the stomach, and that he had fallen to the ground and had remained there until about 3 a. m., when he was found by passers-by who sent him to the hospital.



Hernia of entire stomach resulting from stab wounds.

On examination this tumor proved to be the stomach protruding through the wound. It was nearly perfectly round, dark red, and measured about 10 inches in diameter and was strangulated. A photograph was taken at once by artificial light, after which I had the patient etherized and the tumor elevated as much as possible and turned from one side to the other. The skin was painted with a 5 per cent. solution of iodin beneath the tumor to the edges of the wound, after which the tumor was thoroughly cleansed with saline solution. The lower edge of the stab wound was enlarged. I found that the tumor consisted simply of the entire stomach, and that the stab wound was 1½ inches long diagonally and just beneath the ensiform cartilage, the wound severing the rectus muscle on both sides of the median line. The stomach was gradually reduced into the abdomen, the wound was cleansed with iodin, and the wound layers were sutured, the wound being entirely closed.

The patient made an uneventful recovery with the exception of a stitch abscess which caused some delay in the healing of the wound. He was discharged about November 1, well.

The little white marks seen on the tumor are due to the movements of the tumor during respiratory movement while the photograph was being taken.

Code of Lighting for Industrial Plants.—*Public Health Reports*, Jan. 24, 1919, contains the report of the divisional committee on lighting, section on sanitation, committee on welfare work of the committee on labor, advisory commission, Council of National Defense. It includes a set of rules officially approved by the Illuminating Engineering Society which have been tried out for several years under working conditions in factories, mills and other work places, and which constitutes the basis of the Pennsylvania factory lighting code and that of New Jersey, which went into effect in both states during 1916. The effects of good light in factories are thus set forth in the reports: reduction of accidents; greater accuracy in workmanship; decreased spoilage of product; increased production for the same labor cost; less eye strain; better working and living conditions; greater contentment of the workmen; better order, cleanliness, and neatness in the plant; easier supervision of the men. The article is illustrated, and is an important contribution to the subject of proper light in industrial plants.

THE SUPRARENAL STRUCTURES CONSIDERED FROM NEW POINTS OF VIEW

With the resumption of research activities in the various fields of medical science which were interrupted by the war, the present may be an appropriate time to discard some of the outgrown conceptions that have been handed down in traditional fashion from decade to decade. Acquired hypotheses are always liable to become inherited prejudices which may hamper the progress of science if they are not rigorously subjected now and then to severe critical examination. The current teachings regarding the function of the suprarenal bodies furnish an illustrative case. The brilliant discovery of epinephrin in the suprarenal medulla—a substance capable of affecting blood pressure most profoundly when it is introduced into the blood stream—soon led to the statement that the normal tone of the sympathetic nervous system, particularly as exemplified in its effect on blood pressure, is maintained by an internal secretion from the suprarenals. This conclusion seemed to be fortified by the unquestioned fact that removal of the suprarenal organs is incompatible with the continuance of life. There is an accumulation of experimental evidence, however, some of which has been referred to in the past in The Journal, to indicate conclusively that the normal blood pressure is independent of the suprarenal secretion. A competent reviewer recently concluded that it is indeed doubtful whether under normal conditions a sufficient amount of epinephrin is discharged into the blood of the vena cava to affect appreciably the tone of the blood vessels, and this conclusion seems all the more justified because of the fact that small quantities of epinephrin have a dilating rather than a constricting influence, at least on certain vessels.[1]

There has been a naturally following temptation on the part of clinical observers to ascribe conditions exhibiting high blood pressure, as in arteriosclerosis and certain types of nephritis, to an increase of epinephrin in the blood. The expression "suprarenalemia" has thus attained a limited vogue. The extensive investigations of Stewart and collaborators at the Western Reserve University School of Medicine in Cleveland have, however, tended to render unlikely the explanation of high pressure on the basis of a suprarenal factor. Thus another suprarenal hope has been frustrated. We have also referred in the past to the apparent collapse of the theories so vigorously championed by Cannon with respect to the dependence of reactions to fear and other emotional states on hypersecretion of epinephrin into the blood.[2] So long as it is unproved that the suprarenal secretion can be made to discharge in abnormal amounts through experimental means, it seems hasty to assume a suprarenalemia in conditions of disease or of physiologic emergency.

The negation of so much that has followed the finding of epinephrin, and the appreciation of its pharmacologic potency, need not bring discouragement regarding the discovery of functions for the indispensable suprarenal structures. It is not generally understood by physicians who learned their anatomy in years gone by that what is called the suprarenal body represents the anatomic association of two components, each of which is derived from a separate and independent system. The suprarenal proper, or "cortex," is part of the "cortical" or "interrenal" system. The medulla is simply an accumulation of chromophil cells of the same nature histologically, chemically and pharmacodynamically, as similar masses of cells in other parts of the body. There is no clear evidence that these two systems are functionally related.

At the present time it may be profitable to turn the preponderance of attention away from the medullary part of the suprarenals, on which interest has so long been centered, and to institute inquiries regarding the cortex of the structures. In fact, there is not a little evidence that it is the cortex and not the medulla that is essential to life. Wheeler and Vincent[3] rightly assert that the older extirpation experiments on mammals did not definitely determine the question as to which constituent of the suprarenal body is essential to life, or whether, indeed, it is to the suppression of the compound organ in its entirety that we must attribute death after extirpation. They have furnished instances in which animals have survived, without symptoms, the destruction of the whole or practically the whole of the suprarenal medulla.

Experimental and clinical evidence are combining to indicate that the suprarenal cortex is associated in its functions in some way with the development of the sexual organs. Vincent[4] has reviewed the indications that when cortical tumors occur in the female, an accentuation of male secondary sexual characteristics develops, and simultaneously a hypoplastic condition of the internal generative organs supervenes. Additional evidences as to a connection between the suprarenal cortex and the sexual organs is furnished by the enlargement of the cortex during breeding and pregnancy. Feeding young animals with suprarenal gland substance seems to stimulate the growth of the testes. The present seems to be an appropriate moment to shift, for a time at least, the direction of interest away from the older beliefs, and to attempt to make new discoveries from new angles of attention.

CHILD WELFARE AND DISEASE UNDER WAR-TIME FOOD CONDITIONS IN CENTRAL EUROPE

Reports which are beginning to reach us from central Europe bring confirmation in new ways of the seriousness of the food situation that has confronted the belligerent nations there in the past two or three years. Although an unusually large incidence of epidemics may be interpreted as representing the consequence of widespread malnutrition which offers more ready entrance to the invasion of infections, such a conclusion is by no means the inevitable one. Thus, the outbreak of influenza in many parts of the world can scarcely be adduced as proof of the existence of inadequate food supplies where the malady occurs. But, on the other hand, whenever deficiency diseases come into unusual prominence it may be taken as almost axiomatic that food conditions are somehow disturbed. The accounts of the appearance of "war edema" have focused attention on dietary difficulties referable to war-time conditions. And more recently the descriptions of an unexpected prevalence of infantile scorbutus[1] accentuate the long suspected seriousness of the food situation in the defeated countries.

Even the European pediatricians have at length accepted the inclusion of infantile scurvy in the category of nutritive disorders of the deficiency type. The failure to identify Barlow's disease with what is termed scorbutus in this country appears to be accounted for in large degree by the comparative infrequency of well defined cases. Writing from von Pirquet's clinic for children in Vienna, Tobler remarks that scorbutus has heretofore played only an insignificant part in the pathology of childhood within the ages from 2 to 15. In Gerhardt's "Handbuch für Kinderheilkunde," published in 1878, scurvy in childhood was stated to have practically disappeared. Today, however, it is possible to find reports of literally hundreds of cases of the disease. It is not confined to unhygienic surroundings where "bad air," lack of sunlight, humidity and other once supposedly formidable dangers lurk. Even in the children's homes attached to the great universities of Europe, scorbutus has made its appearance. Underfeeding is not a prime factor, if, indeed, it is a contributory one. Tobler reports that out of sixteen children living at one time in the presumably excellent environment of the solarium of the children's clinic in Vienna, twelve developed scurvy. Hence he dismissed lack of care or unsalubrious climate as an etiologic factor, and refers the genesis of the disease to the protracted exclusive use of foods which have been subjected to certain chemical and physical processes incident to their preparation for the diet. We are told that in the winter of 1917-1918, fresh vegetables and potatoes were no longer available for the children. In one institution only 16 liters of milk were procurable for a personnel of about 500. In 200 carefully studied cases of scurvy, Tobler identified the incidence of the disease with the lack of foods which had not been altered in some way by heat. This corresponds with the numerous reports of the destruction of the antiscorbutic potency of natural foods by heat, as has been pointed out frequently of late in THE JOURNAL.[2]

Reports from Prague are also distressing.[3] The statistics of the average daily gains in weight of children of a certain group in one of the orphanages verify this. From 1913 to 1917 the figure, in grams per day, decreased thus each year: 20.6, 20.5, 17.2, 14.1 and 10.8. The mortality increased from 4 per cent. in 1913 to 15 per cent. in 1917. Various factors have contributed to this unfortunate outcome. Owing to the conditions for which the war was responsible, breast feeding was no longer possible to the same extent as formerly. The nursing women were nourished less well than in the times preceding the war. The failure to secure foster mothers was coincident with an enforced decrease in the supply of cow's milk. The quality of the latter has steadily decreased; and such useful by-products of the milk industry as buttermilk are not available at all.

It is not surprising if, under such trying circumstances, infantile scurvy has conspicuously joined the ranks of other diseases associated with nutrition. Epstein, of the children's clinic in Prague, has given an account of the difficulties confronting therapeutic efforts. The much desired "raw" milk was often of doubtful "rawness," as the high price of milk had taught dairymen to prevent by heat sterilization the loss of even the slightest portion. Oranges, long recommended by English and American pediatricians as antiscorbutics, disappeared from the markets early in the war. Other fruits and even most green vegetables were difficult to obtain and were usually so expensive as to make them almost prohibitive among certain groups of the population. Hence we can understand the earnest appeal of the pediatricians of the afflicted territories for the speedy renewal of the milk supply and their protest against the production of high-priced butter at the expense of infant welfare. In an almost frantic appeal for relief from the impending disaster to European childhood, Epstein has called for action instead of words on the part of the authorities responsible for the public health. We may do well to understand the true import of such warnings so that the nutritive welfare of our own child population shall never be knowingly neglected.

ACUTE INFECTIOUS POLYNEURITIS—A NEW DISEASE

During the war there was observed among British troops a form of polyneuritis of a peculiar character which has been studied with noteworthy results by Bradford, Bashford and Wilson.[1] The clinical manifestations were studied by Bradford in thirty cases.[2] Usually there was first a mild general febrile illness before paralysis appeared, but occasionally paralysis was the first symptom observed. As the primary illness was mild, the symptoms being fever, headache, pain in the back, perhaps vomiting, and sometimes sore throat, no importance as a rule was ascribed to it; at times, however, the condition seemed serious enough to suggest perhaps the possibility of epidemic meningitis. Usually the patient appeared to recover fully in a few days, and then there ensued a variable period of latency, in one case as long as five weeks, before the paralysis which seems to be peculiar to the disease came on. During this interval some of the patients felt well enough for severe physical exertion without distress.

The main characteristics of the paralytic stage were sudden, widespread paralysis, especially, but not exclusively, of the large muscles of the proximal segments of the limbs and trunk; the face also was almost always involved, and generally on both sides; individual muscles or groups of muscles were not picked out, the limbs and trunk being affected as a whole. Though symmetrical, the palsy, which was progressive and sometimes distinctly ascending, was not always equal on the two sides. Atrophy and contractures did not develop. Usually the paralysis was accompanied with pain, numbness, tingling, and relative rather than absolute sensory loss. In declared cases there was loss of tendon reflexes; the sphincters were not profoundly involved. A striking feature was the rapidity with which urgent symptoms and even death came on in patients who seemed to be doing well. In this series of thirty cases death occurred in eight, sometimes rather suddenly, and in all except in one case before the eleventh day of the palsy. In the patients that recovered, the paralysis, first progressive, became stationary and then it would begin slowly to improve.

The results of the work by Bashford on the transmission of the disease to monkeys, and by Wilson on the virus, are remarkable indeed. The main features of the disease were reproduced in monkeys by the subdural injections of suspensions of the spinal cord of three cases after preservation in 50 per cent. glycerol for from twenty-five days to seven months; also by inoculation of cord material from monkey to monkey, and moreover by injection of pure cultures of an organism isolated from the central nervous system. The experimental disease developed after an incubation period of from five to six weeks, but without any recognized and definite preliminary febrile stage, the main symptoms being weakness and paralysis of the limbs, apparently tending to recovery. In anaerobic tissue cultures of nervous tissues from fatal cases and from monkeys, immersed in 50 per cent. glycerol for some days to rid them of gross bacterial contaminations, Wilson obtained growths of a minute, pleomorphic organism, which was difficult to stain and which died out after a few subcultures. Apparently the organism was widely distributed in the nervous system because it rarely happened that a culture failed to give specific growths. If confirmed by subsequent investigators, these results will be highly creditable because of the great difficulties and the many chances of error that attend practically every step in the cultural technic employed in this work.

As regards the gross and microscopic changes in the nervous system, suffice it to say that meningeal congestion, edema, and minute hemorrhages and apparent inequalities in the gray matter of either side of the cord were noted, and that the evidences of acute neuritis and of degeneration of nerve cells with more or less diffuse cellular infiltration in the central nervous system were so definite as to lead the authors to conclude that it concerned a diffuse affection of the nervous system involving the cord, the spinal ganglions and the peripheral nerves, with, however, "but slight incidence on the cortex." The lesions in the central nervous system seem to have been more diffuse than in epidemic poliomyelitis; intense focal changes in the anterior horns, like those seen in the latter disease, seem not to have been observed.

Whatever the final outcome of etiologic and anatomic investigations, there seems little doubt that the English observers have pointed out the existence of a hitherto practically unrecognized disease. The new disease differs from ordinary neuritis in many respects, notably the constant bilateral paralysis of the face, trunk, and proximal segments of the limbs, progressive and at times at least ascending, with involvement of the central nervous system. It would seem to be distinct from epidemic poliomyelitis because there is no muscular atrophy or tendency to contracture, and because the lesions are not identical. Bradford suggests that the virus of the new disease may be a member of the same class as that of epidemic poliomyelitis; possibly epidemic or lethargic encephalitis (nona) is caused by allied organisms. Here are many problems for future work. In the meantime, physicians should bear in mind the probability that there are distinct infectious diseases of the nervous system which may be escaping detection because of a general similarity in their clinical manifestations to established entities.

[2] Gordon Holmes (Brit. M. J. **2**: 37 [July 14] 1917) is said to have described similar cases.

Current Comment

HOSPITAL STANDARDIZATION

The first and most important function of a hospital is to care for the sick and the injured. Many hospitals, however, are engaged in the training of interns and nurses; some are closely related to medical education and some, through research, are adding largely to the world's knowledge in regard to the etiology, diagnosis and treatment of diseases. In recent years also many hospitals have taken on an additional function by having social service workers follow up the patients after they leave the hospital. Where formerly they were merely institutions to care for the sick persons who could not be cared for at their homes, hospitals have now become social institutions, with broadened functions and having a much more intimate relationship with the public in the communities which they serve. In recent years this relationship has increased the general interest in hospitals as public institutions and has pointed to the necessity and importance of their being investigated and regulated—which means standardized. In this connection, the article on hospital standardization by the president of the American Hospital Association, will be of particular interest.[1] In this paper Dr. Warner emphasizes the many and varied interests now centering in the hospital and the equally varied and numerous functions being performed by them. In any efforts toward standardization, therefore, all these interests and functions must be given careful consideration. Not the least factor in the conduct and efficiency of the hospital is the administration, and in this respect hospitals are not unlike hotels with their complex problems of management. In the standardization of hospitals also, the further improvement of both undergraduate and graduate medical education, as well as the function of training interns, and of course nurses also, must be kept in view. The number of hospitals, however, is increasing so rapidly that it will be impossible to supply more than a portion with interns. This brings to the hospital the additional function of training expert technicians and hospital assistants who can perform many of the duties now devolving on interns. The task of standardizing hospitals is a large one, and the many interests involved must work together to establish that standard which will make it possible for these institutions to render the greatest service to the people in the communities in which they are located.

THE END OF A LONG STRUGGLE IN SIGHT

The passage of the public health law in New Mexico, on which we commented last week,[1] marks the beginning of the end of a long campaign for uniform state legislation on vital statistics. Efforts to secure adequate vital statistics legislation were begun almost immediately after the organization of the American Medical Association in 1847. Yet in 1906 there was no birth registration worth mentioning, while only ten states had any death registration. In 1907, the so-called model bill was drafted, through the united efforts of the federal Bureau of the Census, the Committee on Legislation of the American Medical Association, and the Committee on Vital Statistics of the American Public Health Association. Numerous professional and social organizations endorsed the measure, and the work of securing its adoption in the different states was taken up systematically and carried on from year to year. Quietly but steadily this movement has gone on, with the result that the passage of the law in New Mexico leaves Arizona and Nevada as the only states without provisions for birth and death registration. Forty-one states have now adopted satisfactory laws. In Delaware, South Dakota, Iowa, West Virginia and Alabama, the laws are not satisfactory for several reasons, the chief difficulty arising from adherence to the obsolete and ineffective method of registering deaths through county clerks rather than through local registrars under the control of a state registrar. These inconsistencies will without doubt be corrected in the near future. In fact, bills are at present before the legislatures of Alabama and West Virginia for the reorganization of their vital statistics methods. The Arizona legislature meets in November of the present year, when it is hoped that the model bill will become a law. This would leave only Nevada to adopt the law at the next session of her legislature. If the physicians and the public spirited citizens of Arizona will interest themselves in this matter, there will be no difficulty in adding Arizona to the list of states enjoying modern and effective birth and death registration.

STANDARDIZATION OF DEGREES IN PUBLIC HEALTH

In our correspondence column this week appears a report regarding an effort to standardize degrees in public health. This is an important and timely subject not only in its relation to courses in public health but also in its bearing on degrees for other creditable graduate work. An individual who has creditably pursued a definite course of graduate instruction deserves to have a suitable degree. At the same time a multiplicity of degrees should be avoided. The report referred to suggests the degree of Doctor of Public Health (Dr.P.H.) for graduates in medicine after two years of work, of which at least one has been in residence. This is a wise suggestion which might well be adopted by all universities giving degrees in public health. Three years ago there were seven institutions which reported courses leading to the degree of Doctor of Public Health, and only three[1] required the two year course, while the others[2] required a one year course. One other institution, the University of California, granted the degree of Graduate in Public Health (Gr.P.H.) on completion of a two year course. To avoid confusion, one degree must be awarded for work of similar character; and to give the degree a real value, it must represent a definite amount of work. It is encouraging also to note that for a three year graduate course, for students holding the bachelor degree from a college or technical school, the report suggests either the degree of doctor of philosophy (Ph.D.) or of Doctor of Science (Sc.D.). The former degree is seldom granted as an honorary title while on the contrary the latter degree is honorary in the majority of instances. It would appear, therefore, that the doctor of philosophy (Ph.D.) degree is preferable. As to whether the character of the work done should be designated by such phrases as "in Public Health and Hygiene," there appear to be differences of opinion. So long as a degree used represents a definite amount of creditable graduate work, it would not seem necessary to add a lot of supernumerary letters to indicate the particular kind of work done.

INCREASED HARRISON LAW TAX UNJUST TO PHYSICIANS

While the Harrison law for the control of narcotic drugs was passed ostensibly for the purpose of raising revenue, it is in reality a public health measure. The revenue feature is only a legal subterfuge, as it was only by imposing a tax that Congress could exercise any jurisdiction on the question. The tax, therefore, being merely a pretext, should be a minimum and purely nominal one. Originally, the law required physicians who desire to prescribe the drugs covered by the act to pay an annual registration fee of one dollar. There are approximately 150,000 physicians in the United States. The law, therefore, imposed a tax of $150,000 on the medical profession for the protection of the public. This tax physicians cheerfully paid, accepting this small burden for the sake of the public benefits to be derived from the measure. However, at the last session, Congress, in the revenue law, increased the fees for registration under the Harrison law. The license fee for physicians was increased to three dollars. This means that physicians in the United States will be required during the next year to contribute nearly half a million dollars, purely for the public good and not in any sense for the benefit of the profession. The Harrison law is of no special benefit to physicians. The Journal, the American Medical Association and the American medical profession enthusiastically supported the Harrison bill when it was before Congress. The great majority of the profession have cooperated to the extent of their ability to promote the enforcement of the law. The nominal tax of one dollar was accepted by physicians as necessary to validate the measure. But there is not the slightest excuse, either legal or social, for increasing this fee to three dollars. If the expenses of administering the law are greater than the revenue derived from it, sufficient appropriation should be made out of the public money derived from general taxation. The law is for the benefit of the public, and the public should pay for it. It is, of course, too late to secure any change in the situation for the present year, but the law should be amended at the first opportunity by restoring the nominal tax of one dollar. If our state and county societies will bring this situation to the attention of their congressmen and will demand the amendment of the present law, speedy correction of the injustice done the profession will be possible.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending March 21, the Medical Corps contained 20,243 officers, a decrease of 437 from the previous week. The Medical Reserve Corps contained 1,198 officers. The total number of medical officers discharged since the beginning of the war is 13,279.

Air Service Division of the Office of the Surgeon-General Discontinued

The Surgeon-General's Office announces that the Air Service Division of that office, which was established for the purpose of handling medical problems connected with the aviation service, has been discontinued. The business of that division will be taken over by the air service under the jurisdiction of its chief surgeon.

Officers Appointed in Medical Corps of Navy

One hundred and forty-eight temporary and reserve officers have been appointed in the regular Medical Corps of the Navy as a result of recent examinations. These officers have served during the war in a temporary capacity. Thirty-eight were temporary officers and the remainder members of the reserve corps.

Promotion in Army Medical Corps

The provisions of section 10 of the national defense act relative to promotions in the Army Medical Corps, suspended by the act of Oct. 6, 1917, were again made operative from December 10. All officers who had completed one year's service prior to December 10 have been promoted. However, since the suspension of the act of October 6, which removed for the period of the war the requirements that lieutenants in the Medical Corps shall serve five years before being entitled to a captaincy, no service except that rendered under a permanent commission counts toward promotion.

General Pershing Thanks the Medical Corps

Following is the copy of a letter dated Feb. 20, 1919, from the commander-in-chief of the American Expeditionary Forces to Col. Walter D. McCaw, M. C., chief surgeon, A. E. F.:

My dear Colonel McCaw:

Now that active operations are at an end, and many officers and enlisted personnel are preparing to sever their connection with the military forces and return to civil life, I desire to express my personal appreciation and thanks and that of your fellow members of the American Expeditionary Forces to you, and through you to the members of your Department, for the splendid services they have rendered.

At the front and in the long chain of hospitals extending down to the Base Ports, I have watched the fine and unselfish character of their work, and the achievements which have added new glory to the noble professions they have so ably represented. Many of them have shared with the line troops the hardships of campaign conditions and have sustained casualties and privations with fortitude that is beyond praise. No labor has been too exhausting and no danger too great to prevent their full discharge of duty.

---

[1] These are the Schools of Public Health of the Universities of Colorado, Michigan and Wisconsin.

[2] These are the Schools of Public Health of Harvard, Tulane, University and Bellevue, and the University of Pennsylvania.

A special word of thanks is due to those members who were attached to and served continuously with the armies of our Allies. Their efficiency and high ideals have called for the highest praise of the Allied Governments under whom they have served.

Before they leave France, will you convey to all ranks under your command the deep sense of my personal appreciation of their splendid services and my regret at the impracticability of sending each and every one of them a letter of thanks?

Sincerely yours,
John J. Pershing.

Wax Models of War Wounds

An important work now being carried on by the Medical Department of the Army is the preparation of various lesions of the skin in wax showing the nature of wounds and diseases during the late war. Wax reproductions are being made in the Army Medical Museum by an expert of the following types of cases: chronic or unhealed ulcers following various types of wounds; unhealed lesions resulting from gas burns; unusual scar formations, and unusual skin diseases. It is the intention of the Medical Department of the Army to order patients in especially interesting cases of this character to the Walter Reed Hospital for further treatment and for the production of the models, which will be a permanent exhibit in the Army Medical Museum.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

ALABAMA

New Medical Society.—A meeting of the physicians of Bessemer was held in the circuit court rooms, February 14, for the purpose of organizing a medical society.

Marine Hospital to Be Enlarged.—The United States Marine Hospital at Mobile is to be enlarged at an expense of $100,000. Quarters are to be erected for the personnel of the official staff, and the present quarters are to be converted into wards for patients. This will double the capacity of the hospital, which will then be able to accommodate 100 patients.

Personal.—Dr. Henry B. Wilkinson, Montgomery, began his duties as county health officer of Montgomery County, March 1, succeeding Dr. Carney G. Laslie. Dr. Wilkinson has also been selected as chairman of the committee on sanitation and health in the work division of the chamber of commerce to succeed Dr. Paul S. Mertins, resigned.——Dr. Arthur A. Kirk, Tuscaloosa, has been named as full-time health officer of Tuscaloosa County, succeeding Dr. Charles M. Murphy, Aliceville, resigned.——Dr. George A. Cryer, Anniston, has been elected health officer of the unified district of Anniston and Calhoun County.——Dr. John S. Tucker, Blocton, has been appointed convict physician at Belle Ellen Mines.——Dr. Russell A. Smith, Brewton, physician inspector in congress in Alabama, has resigned.——Dr. Charles A. Mohr has been elected full-time health officer of the city and county of Mobile.

ARKANSAS

Personal.—Dr. Eustis J. Chaffin, Hughes, was wounded, February 15, in a fight with a negro, who was later killed by the physician.

Health Officers' Conference.—The sixth annual conference of city and county health officers of the state was held in Little Rock, February 27 and 28, under the presidency of Dr. Charles W. Garrison, Little Rock, state health officer.

New Officers.—Little River County Medical Association at its annual meeting in Foreman, February 26, elected Dr. John W. Ringgold, Ashdown, president; Dr. Wesley L. Shirey, Foreman, vice president, and Dr. William E. Vaughan, Richmond, secretary-treasurer.——Phillips County Medical Society at Helena elected Dr. Aris W. Cox, Helena, president; Dr. John W. Bean, Marvell, vice president, and reelected Dr. Montague Fink, Helena, secretary-treasurer.——At the meeting of the Mississippi County Medical Society held at Osceola Dr. Isaac R. Johnson, Blytheville, was elected president; Dr. William J. Sheddan, Osceola, vice president, and Dr. Earl E. Craig, Wilson, secretary-treasurer.

FLORIDA

Personal.—Dr. William D. Nobles has been reappointed a member of the health department of Pensacola.——Dr. Charles L. Jennings, Capt., M. C., U. S. Army, Jacksonville, on duty with Evacuation Hospital No. 9, who accompanied the Army of Occupation to Coblenz, has returned home.——Harper L. Proctor, Capt., M. C., U. S. Army, Jacksonville, attached to the 163d Aero Squadron, has returned from France.

Annual Meeting of Florida Board.—At the annual meeting of the Florida State Board of Health held in Jacksonville, March 7, new legislation was discussed. Dr. Calvin T. Young, Plant City, was appointed district health officer in charge of the Lakeland district. Dr. John Keeley, district health officer of Jacksonville, was transferred to Miami district, and Dr. W. H. Bryan was transferred to the Jacksonville district. Dr. Grace L. R. Whitford, Ozona, head of the child welfare bureau, will hereafter make her headquarters at Tampa and has been given an assistant, Dr. M. Josie Rogers, Daytona.

ILLINOIS

Smallpox in Peoria.—It is reported that there have been seventy-five cases of smallpox in Peoria. Vaccination of all schoolchildren who had not been vaccinated during the last three years has been ordered by the state board of health.

County Tuberculosis Hospital.—The Christian County Tuberculosis Board has been organized with Thomas J. Verler, Pana, chairman; Jesse P. Patterson, secretary-treasurer, the third member of the board being Dr. Thomas A. Lawler, Taylorsville. Christian County voted last November to establish and maintain a tuberculosis sanatorium for Christian County.

Personal.—Louis Ostrom, Capt., M. C., U. S. Army, Rock Island, on duty with Evacuation Hospital No. 49, is now with the American Army of Occupation at Coblenz, Germany.——Dr. John F. Brown, Kankakee, has been appointed superintendent of the Central Hospital for the Insane, Waupun, Wis., succeeding Dr. L. Rock Sleyster.——Dr. James W. MacDonald, Aurora, has been appointed a director of the Kane County Tuberculosis Sanatorium.

Chicago

Personal.—Selim W. McArthur, Capt., M. C., U. S. Army, formerly connected with Base Hospital Unit No. 14, has been ordered to Coblenz, Germany.——David S. Hillis, Lieut.-Com., M. C., U. S N. R. F., has returned from service in the Navy.

Dinner to Dr. Hunt.—The Vassar Alumnae Association of Chicago and the West gave an informal dinner, March 25, in honor of Dr. Barbara Hunt, Bangor, Me., of the American Women's Hospitals, who has just returned from service in France and who delivered an address, illustrated with stereopticon views. Dr. Alice Hamilton of the United States Department of Labor, associate professor of industrial medicine in the Medical School of Harvard University, also spoke.

IOWA

New Officers.—At the annual meeting of the Cerro Gordo County Medical Society held at Mason City, Dr. Stella M. Mason was elected president, Dr. Frank G. Murphy, vice president, and Dr. Stephen A. O'Brien, secretary-treasurer, all of Mason City.

Smallpox in Davenport.—March 5 and 6, seven cases of smallpox were reported in Davenport. Three of these cases have been taken to St. Robert's Hospital and the four other cases have been quarantined.——On March 8, eleven cases were found in one family which had been treated by a chiropractor.

Personal.—Dr. Lillie A. Arnett, Cedar Falls, has returned after service abroad with the Red Cross in France.——Edwin A. Merritt, Major, M. C., U. S. Army, Council Bluffs, who returned to America in March, has been promoted to lieutenant-colonel. He has been in charge of field roentgen-ray units with the Army of Occupation.——Dr. Harry P. Mason, Wilton Junction, has been reelected a member of the school board of Wilton.——Dr. Cassius L. Campbell, Atlantic, has been reelected a member of the board of education of Atlantic.——Emil O. Ficke, Capt., M. C., U. S. Army, Davenport, has returned to his home after seven months' duty in France.

LOUISIANA

Board of Health Annex.—At a meeting of the Louisiana State Board of Health, February 20, it was announced that a building had been purchased in New Orleans for $3,000 for the use of the board. The building will be remodeled.

Health Service Transferred.—The formal transfer of the Public Health Service from the United States to the city of Alexandria, the parish of Rapides and the state of Louisiana, was made, March 7, at a conference between Dr. Oscar Dowling, Shreveport, president of the state board of health; Capt. H. F. Smith, who has been in charge of the service since the establishment of Camp Beauregard; the mayor of Alexandria; commissioners Hunter and McGinnis, and Dr. C. W. Abbott.

Sale of Habit-Forming Drugs Curbed.—Two shipments of morphin consigned to New Orleans druggists have been confiscated by the president of the state board of health under the state law governing the sale and handling of narcotics.——The state board of health at its session, February 21, revoked the licenses of five physicians of New Orleans for prescribing habit-forming drugs, and the license of one New Orleans druggist was revoked. The licenses of a number of country physicians were also revoked for the same offense.

MARYLAND

Personal.—Col Hugh H. Young, Baltimore, who recently returned from France, addressed the Baltimore Life Underwriters' Association at their annual banquet, his subject being the health conditions among the American soldiers.

Anniversary of West End Medical Association.—The first anniversary of the West End Medical Association of Baltimore was celebrated on March 21 by a clinic at the Franklin Square Hospital in the afternoon and a banquet at the Hotel Emerson in the evening. Health Commissioner John D. Blake was the speaker at the banquet and made an address on "The Health of Baltimore." Dr. Asa L. Wessels is the president; Dr. Charles S. Parker, vice president; Dr. William A. Knell, secretary, and Dr. Egbert L. Mortimer, treasurer.

Mumps Prevalent in Baltimore.—Mumps is prevalent in Baltimore, the northern and western sections being especially affected. One hundred and forty-eight new cases were reported to the health department during last week, but it has been more or less epidemic in the city for several months. Many of the cases are accompanied by severe vomiting and an unusual proportion of those affected are adults. Of scarlet fever 178 cases were also reported to the health department during the past week. They are widely scattered all over the city.

MICHIGAN

Medical Staff Organized.—The medical staff of St. Joseph's Hospital, Menominee, organized recently, electing Dr. Walter R. Hicks president, Dr. Stephen C. Mason secretary-treasurer, both of Menominee, and Dr. George F. Colter, Marinette, Wis., chairman of the executive committee.

Tuberculosis Publication for the Public.—The Michigan Anti-Tuberculosis Association has adopted a plan of limited circulation for its new magazine, *Michigan Out-of-Doors.* The publication may be obtained by sending a postal card request giving name and address to the Michigan Anti-Tuberculosis Association, Science Building, Detroit.

Personal.—Angus McLean, Col., M. C., U. S. Army, director of Base Hospital No. 17, A. E. F., for twenty months past, has returned to Detroit. Walter D. Ford, Major, M. C., U. S. Army, Detroit, commander of the unit returned on the same transport.——Leo J. Dretzka, Capt., M. C., U. S. Army, Detroit, has returned from overseas.——Dr. William K. Wright, Manistique, is ill in a hospital in Chicago suffering from carcinoma of the intestine.——Dr. Matthew B. Smith, Fenton, suffered severe cuts and bruises when his car was wrecked by a motor truck, March 3.

MINNESOTA

Reconstruction Work.—At a noonday meeting in St. Paul, March 12, W. S. Miller, Capt., U. S. Army, chief of the educational service at Fort Snelling, gave a talk on reconstruction work at Fort Snelling.

Personal.—Dr. Harry M. Guilford, health commissioner of Minneapolis, is ill with diphtheria and is under treatment at the City Hospital.——Dr. Edward T. Sanderson, Minneota, and Dr. Frank D. Gray, Marshall, have been appointed members of the executive board of the Lyon County Public Health Association.

MISSOURI

Personal.—Dr. George B. Mangold has been elected first vice president and Louis P. H. Bahrenburg, Surg., U. S. P. H. S., medical director of the St. Louis Tuberculosis Society.——Dr. William C. Baird, Bogard, fell on the ice, March 4, fracturing his clavicle and sustaining severe bruises of the hip and right hand.——Dr. Julien A. Gehrung, St. Louis, who has been on duty with the French army since February, 1917, has returned from France.

Missouri Officers Association Formed.—The Missouri Officers' Association is the name of an organization recently formed for the purpose of perpetuating the association of army officers from Missouri who served during the recent war. It is an outgrowth of the Fort Sheridan and Fort Riley association. All medical officers in Missouri who desire to affiliate should address the Missouri Officers' Association, 304 Rialto Building, St. Louis.

Reconstruction Hospital Completed.—The government reconstruction hospital at St. Louis will probably be completed and ready for occupancy by the injured soldiers, April 1. The building taken over by the government is the one formerly used by the city of St. Louis for housing its infirm and decrepit who have become charges on the city's bounty. These unfortunates have been transferred to the commodious building and grounds formerly occupied by the Christian Brothers College which the city has purchased. The government has spent $700,000 in remodeling and equipping the building to be occupied by the wounded soldiers. A staff of about forty-five army surgeons and eighty nurses will be assigned to the institution which has been constructed to accommodate about 1,000 patients. The equipment will be thorough and complete in every respect and it will be one of the best equipped institutions of the kind now under control of the Medical Department of the Army.

MONTANA

Temporary Health Officer.—Dr. Albrecht D. Eckardt, Helena, who recently received his discharge from the Army, has accepted a temporary appointment as health officer of Bozeman.

Fine for Violation of Drug Act.—Dr. Charles Pixley, Missoula, indicted by the federal grand jury on the charge of violation of the federal law regulating the issuance of habit-forming drugs, and also for failure for two years past to keep a record of prescriptions for such drugs, as required by law, is said to have pleaded guilty in the United States district court, March 10, and to have been fined $100 and costs.

NEBRASKA

Board of Health Bill.—February 5, a bill providing for municipal boards of health in cities of from 5,000 to 25,000 population and limiting the jurisdiction to municipal boundaries, was read a third time and passed.

Personal.—Dr. Samuel J. Stewart, Hastings, has been appointed a member of the advisory board to the state board of health, succeeding Dr. Hall H. Humphrey, Daykin.——Dr. W. W. Kohler, Lexington, is reported to be ill in Los Angeles.

Medical College Fund Suffers.—The legislative finance committee has eliminated the proposed appropriation of $40,000 for a laboratory for the University of Nebraska College of Medicine, Omaha; has reduced the appropriation for new equipment at the University Hospital from $30,000 to $20,000 and the appropriation for maintenance of the hospital from $150,000 to $125,000.

Hospital News.—Drs. S. R. Ayer and Luman B. Swaggart, McCook, have purchased the McCook General Hospital, which was owned and operated by the late Dr. David J. Reid.——The Good Samaritan Hospital, Kearney, has secured a site and a campaign has been launched to raise $100,000 for the erection and equipment of the hospital, which will have accommodations for fifty patients.

NEW JERSEY

Personal.—Mr. T. W. Margerum, Princeton, health officer, registrar of vital statistics, and bacteriologist of Princeton and Princeton University, has succeeded Charles L. Williams, Asst. Surg., U. S. P. H. S., as head of the city health department of Macon, Ga.

NEW YORK

Personal.—Daniel E. Pugh, Jr., Capt., M. C., U. S. Army, Elmira, arrived in New York on his return from France, March 6.——Pearce Bailey, Col., U. S. Army, New York City, has been released from military duty and has been appointed medical chairman of the state commission for the feebleminded to succeed Dr. Walter B. James, resigned.

Diphtheria in Sing Sing.—Reports from Sing Sing Prison state that, March 16, there were sixty-five prisoners down with diphtheria, twenty-five of these having been reported within twenty-four hours. Influenza is still more or less prevalent in the institution and that with other ailments brings the total number of patients up to 115, which has necessitated bringing in additional medical and nursing care from outside.

Hearing on Health Insurance Bill.—According to an announcement made by Senator Davenport the Davenport-Donohue bill which provides for compulsory health insurance has been amended to meet some of the objections made by physicians. Chief among the amendments is a provision by which physicians will not be on a salary, but will be paid according to services rendered under the schedule of fees to be approved by the state industrial commission and which may vary according to local conditions. Provision is made for hearings on the schedules so that they may be revised from time to time. Provision is also made for the free choice of a physician by the patient, thus eliminating the panel originally provided for. Perhaps the most important change in the bill is that which provides that the head of the proposed bureau of health insurance shall be a physician. It is estimated that the cost of this insurance will be 24 cents a week each to employer and employee. At the public hearing, March 19, opponents of the bill stated that according to their estimate it would cost $5,000,000 a year to administer the bill instead of $3,500,000 as the sponsors of the bill claim. Among the opponents of the bill appearing at the hearing were merchants, manufacturers, physicians and fraternal orders. The spokesmen for the bill were the labor unions and women's organizations.

New York City

New Maternity Clinics.—The New York Milk Committee as a part of its plan for extending antenatal work has opened three new maternity clinics in the Bronx, one at the Bronx House, 1637 Washington Avenue; a second at 2380 Hughes Avenue, and a third at 513 East One Hundred and Forty-Ninth Street. Among those speaking at the formal opening of these clinics were Drs. John H. Telfair, Morris L. Ogan, Ralph W. Lobenstine and Arthur J. O'Leary.

Conference on Rehabilitation.—The Red Cross Institutes for Crippled and Disabled Men held a conference which was international in scope at the Waldorf, from March 18-21, at which there were representatives from France, England, Belgium and Italy, and thirty delegates from Canada. The American agencies which were represented included men and women from the office of the Surgeon-General, the Army, the Federal Board for Vocational Education and the Bureau of War Risk Insurance. A closing mass meeting was held on Sunday afternoon at the Hippodrome at which Charles E. Hughes presided. Dr. Maurice Bourillon, president of the permanent interallied committee on war cripples and director of the French national institute for crippled soldiers, described the beginning of the making over a 694,000 Frenchmen incapacitated by war diseases or wounds. It was stated at the meeting that of the men returning from overseas at least 100,000 are not unscathed, being crippled, blinded or gassed and will need the grateful help of America before they can take the place they have earned in life. Dr. C. A. Prosser, director of the Federal Board of Vocational Reeducation, estimates that the number who will require vocational reeducation will reach 20,000.

NORTH CAROLINA

State Society to Meet.—The annual meeting of the Medical Society of the State of North Carolina will be held at the Carolina Hotel, Pinehurst, April 15-17, under the presidency of Dr. Cyrus Thompson, Jacksonville.

Urologic Clinic Chartered.—The Crowell Urological Clinic of Charlotte has been incorporated with a capital stock of $125,000, by Drs. Andrew J. Crowell, Robert H. Lafferty, Joseph A. Elliott and S. Raymond Thompson.

Hospital to Reopen.—The Wesley-Long Hospital, Greensboro, will be reopened about April 1, and will be under the charge of John W. Long, Lieut.-Col., M. C., U. S. Army, who has just been discharged, after having been in service since June, 1917, in this country and with the American Expeditionary Forces in France.

Clinic for Charlotte.—A conference of physicians was held at the city health office, Charlotte, March 8, at which Dr. Carl Fellers discussed with the medical men the projected establishment of a clinic for venereal disease, to be operated jointly by the city of Charlotte and Mecklinburg County, with financial aid from the state and the United States Public Health Service.

Personal.—Marshall H. Fletcher, Major, M. C., U. S. Army, Asheville, who has been in command of Base Hospital No. 65, Kerhoun, France, has been discharged from service, and will resume practice in Asheville.——Dr. Harvey P. Barret has been elected city bacteriologist of Charlotte, succeeding Lloyd R. Jones, Asst. Surg., U. S. P. H. S., who has been transferred to Fayetteville.

Mosquito Eradication.—The United States Public Health Service will give the city of Wilmington $10,000 for the continuation of the work of mosquito eradication, provided an appropriation of like amount is made by the city of Wilmington and New Hanover County. The work already done has included the digging of 20 miles of ditches, the clearing of 17½ miles of streams, the construction of 1½ miles of dikes, the installation of six tide-gates and the spraying of large quantities of crude oil over the waters of the swamp lands.

OHIO

Personal.—Dr. Harry L. Rockwood, acting health commissioner of Cleveland, since Dr. Robert H. Bishop, Jr., went to Italy with the American Red Cross Tuberculosis Mission, has resigned and expects to enter private practice.——Henry M. Pearce, Capt., M. C., U. S. Army, Urbana, recently discharged after a year of service overseas with the Eighty-Third Division, is reported to be critically ill with meningitis.——F. Dale Barker, Capt., M. C., U. S. Army, Dayton, has returned from overseas.——Dr. Charles A. LaMont has resigned as city health officer of Canton, to take effect April 1.

OREGON

Personal.—Dr. George Parrish, city health officer of Portland, who has been away on leave of absence for two months, has returned and has resumed his duties.——Dr. John G. Abele, who has been serving as acting city health officer of Portland, has now become first assistant health officer in charge of contagion in Portland.——Drs. Calvin S. White, G. Norman Pease and Harold C. Bean, all of whom have served in the Army in this country or abroad, have been added to the staff of Reed College Clinic, Portland.——Dr. Rasmus P. Mortensen, Springfield, underwent operation for tuberculosis of the intestines in a Portland hospital, February 27.——Frank R. Mount, Major, M. C., U. S. Army, Oregon City, and on duty with the A. E. F. in France, has been promoted to lieutenant-colonel, M. C.——Edwin W. Morse, Capt., M. C., U. S. Army, Portland, on duty with Base Hospital No. 46, returned, February 25, after nine months' service in France.——Fred A. Lieuallen, Capt., M. C., U. S. Army, Portland, on duty with the Forty-Seventh Infantry, A. E. F., in France, thrice cited for bravery, has been discharged, disabled from having been gassed, and has returned to Portland.

PENNSYLVANIA

Philadelphia

Personal.—Dr. Percival M. Kerr, Elwyn, medical attaché to Admiral Wilson and former member of the Methodist Hospital Unit, has returned from France where he has been since October, 1917.——Dr. Orlando H. Petty, Lieutenant in the Naval Reserve Force, has been awarded the Distinguished Service Cross for extraordinary heroism.——Dr. H. H. Wickert, now serving with the Episcopal Hospital Unit No. 34, with the Army of Occupation, has been promoted to the rank of major. He enlisted in the British army before this country entered the war and subsequently was transferred to the Episcopal Hospital Unit.——Drs. Edward Martin and John D. McLean, commissioner and assistant commissioner of health of Pennsylvania, will be the guests of honor at a dinner given by the Philadelphia Clinical Association and other medical organizations in and near Philadelphia, at at Bellevue-Stratford, April 10.

SOUTH CAROLINA

Personal.—Dr. William O. Wrightson, who has just been discharged from the Medical Corps, U. S. Army, has been appointed director of health of Spartanburg, succeeding Hugh D. Ward, P. A. Surg., U. S. P. H. S.——Dr. James C. Mitchell, Anderson, formerly health commissioner, who has just returned from army service, has been reappointed to that position, succeeding Dr. E. R. Vandergrift, resigned.——H. F. White, P. A. Surg., U. S. P. H. S., who has been in charge of the work of the service in Greenville and the surrounding territory since April, 1918, and who served for several months as health commissioner of Greenville, has been ordered to other duties. The city council, at a special meeting, February 25, adopted resolutions of thanks and appreciation.

SOUTH DAKOTA

Personal.—Dr. James O. Lee, Pierre, has been appointed physician and surgeon of the U. S. Indian School, Pierre, succeeding Dr. Charles M. Hollister.

New Clinic.—The old Methodist Church property, Sioux Falls, has been sold to Drs. Thomas J. Billion, Monte A. Stern, Earl E. Gage, Nelius J. Nessa, Guy E. VanDemark, George A. Stevens, Edwin L. Perkins and Roy G. Stevens. On this site will be erected a building at a cost of $60,000, to be known as the Sioux Falls Medical and Surgical Clinic.

TENNESSEE

State Association to Meet.—The Tennessee State Medical Association will hold its eighty-sixth meeting in Nashville, April 8-10, under the presidency of Dr. Richmond McKinney, Memphis.

Personal.—Dr. William Krauss, Memphis, has been elected medical director of the Memphis and Shelby County Anti-Tuberculosis Society, and Drs. A. B. Curry, William T. Pride, William Krauss, T. W. Lewis, Harry F. Minor and Cooper Battle are the medical members of the board of directors.

Endowment for Meharry.—Report states that the General Education Board and the Carnegie Foundation for the Advancement of Teaching have each voted to give $150,000 for the endowment of Meharry Medical College, Nashville, provided the Methodist Episcopal Church will raise $200,000, which would make a total of $500,000. From the standpoint of number of students enrolled, Meharry Medical College is the largest negro medical school in the country.

City to Take Over Federal Clinic.—The city of Chattanooga has arranged to take over the operations of the federal government venereal clinic, located in the city hall, under the charge of Asst. Surg. Carlisle P. Knight, U. S. P. H. S. Dr. Stanton S. Marchbanks will be left in charge of the clinic.——Col. Mack Morris, formerly of Trenton, now of Jackson, has offered to donate to the city of Trenton a hospital to cost not less than $15,000. The only obligation to the city is to keep the hospital in as good a condition as it was when presented.

TEXAS

New Editor.—Dr. Paul Gallagher, El Paso, has been elected editor of the *Southwestern Medical and Surgical Journal* in place of Dr. Elliott C. Prentiss who has resigned.

Chiropractor Fined.—It is reported from El Paso that Dr. Byron Black, a chiropractor, was found guilty of practicing medicine without a license and sentenced to a day in jail and a fine of $250.

New Officers.—Bee County Medical Society at its annual meeting held in Beeville elected Dr. Lawrence L. Griffin, president; Dr. Andrew J. Turner, vice president, and Houston Neeley, secretary.

Hydrophobia Bill Passed.—The senate committee on public health has reported favorably on the Hertzberg bill which provides for the free treatment of hydrophobia at the State Pasteur Institute, Austin.

New State Board Officers.—At a meeting for organization of the new state board of medical examiners held in Waco, February 28, Dr. William C. Swain, Dallas, was elected president; Dr. E. Marvin Bailey, Houston, vice president, and Dr. Manuel F. Bettencourt, Mart, secretary.

City Takes Over Laboratory.—Formal transfer of all the equipment in the United States Public Health Service laboratory at Fort Worth was made to the city health department, February 11. This is the first step in taking over by the city all the health work heretofore carried on by the federal government.

Bill Passed to Establish State Quarantine.—The senate committee on public health rendered a favorable majority report, February 18, on the Fly house bill which provides for turning over to the federal quarantine authorities the state quarantine stations and matters at gulf ports and along the border.

Personal.—William B. Carrell, Capt., M. C., U. S. Army, Dallas, on duty at the Orthopedic Hospital, Bordeaux, France, has been promoted to major.——Robert Finney Miller, M. C., U. S. Army, who has been in France for more than a year, has returned to his home, near Gay Hill.——William L. Crosthwait, Major, M. C., U. S. Army, Waco, who has been on duty at Base Hospital No. 55, A. E. F., in France, has been discharged and has returned home.

Health Association Meeting.—At the annual meeting of the Texas Public Health Association held in Austin, February 12, the following officers were elected: William A. Bowen, Arlington, president; Drs. Elva A. Wright, Houston, and Beverly T. Young, San Antonio, vice presidents; Dr. Zachary T. Scott, Austin, secretary, and H. A. Wroe, Austin, treasurer. In addition to the officers named the following were elected members of the board of directors. Drs. C. B. Baird, Dallas; William M. Brumby, Waco; Orville T. Bundy, Hutto; Ira C. Chase, Fort Worth; Boyd Cornick, San Angelo; Robert B. Homan, El Paso; John S. Lankford, San Antonio; Joseph B. McKnight, Carlsbad; Frank Paschal, San Antonio, and C. W. Goddard, Austin. During the year more than 400,000 pieces of literature bearing on public health were distributed, more than 300,000 children were organized in the modern health crusade movement, and more than 30,000 personal letters were written by the association.

WASHINGTON

Chinese Doctor Held.—Sing Lock of the Sing Lee Chinese Medicine Company, Seattle, it is reported, was arrested, March 5, on charges of having opium in his possession and was released on bail of $500.

Personal.—Dr. Albert E. Stuht, Spokane, was sent, March 7, to Olympia by the Spokane County commissioners, to urge the passage of Senate Bills 6 and 96 which have reference to the isolation of individuals suffering from venereal disease.——Dr. Howard H. Smith has been appointed health officer of Yakima city and county succeeding Dr. Benjamin S. Cerswell, North Yakima. He takes office June 5.——Dr. John B. Anderson, resigned, March 4, as health officer of Spokane, to resume duties as state health commissioner.——Ralph Hendricks, Major, M. C., U. S. Army, who is expected to return from France before May 1, has been appointed health officer of Spokane.——Harry C. Blair, Lieut., M. C., U. S. Army, Tacoma, a member of Base Hospital Unit No. 46, arrived in Tacoma, February 23, after seven months in France.——Dr. Jesse J. Tilton, Spokane, has been elected a member of the board of directors of the Social Service Bureau.——Dr. Perry W. Cornue, Yakima, has been elected president of the Illinois Club.

CANADA

University News.—McGill University will erect a memorial hall to honor her fallen graduates and undergraduates. It will be a convocation hall and will cost about $150,000.

Personal.—Col. John M. Elder, Montreal, has returned from overseas.——The name of Sir Auckland C. Geddes, Montreal, formerly professor of anatomy in the University of McGill, is mentioned to succeed Sir William Peterson in the principalship should the latter not be able to continue his official duties on account of having recently suffered a paralytic attack.——Col. George E. Armstrong, C.M.G., Montreal, has become consultant in surgery at the Royal Victoria Hospital, Montreal.——The Hon. Dr. Robert A. Pyne, Toronto, formerly minister of education for Ontario, has been appointed to the board of governors of the University of Toronto.

Hospital News.—Ottawa, Canada, is asking permission of the Ontario legislature to raise $1,500,000 for establishing a civic hospital.——A citizen of Kitchener, Ont., offers $25,000 for a nurses' residence in connection with the Kitchener-Waterloo Hospital, provided $10,000 can be raised by the board from public subscription.——The government of Quebec and the government of Canada will provide the funds for enlarging the Ste. Agathe Sanatorium, Quebec, so as to increase the accommodations from 70 to nearly 300 beds. The extensions are to cost in the neighborhood of $300,000, and the institution will be used for five years for tuberculous soldiers.——Vancouver is to have a new emergency hospital. The entire cost will be about $30,000. The provincial government of British Columbia will contribute $15,000.——The Toronto city council has been asked for a grant of $40,000 toward liquidating the deficit of the Hospital for Sick Children which amounts to $89,753.——An addition is to be erected to the Royal Victoria Hospital, Montreal, at a cost of $12,000.

Ontario Social Hygiene Committee.—Following up the interim report on venereal diseases in Ontario, Mr. Justice Hodgins, who sat as royal commissioner, has presented a second report to the Ontario government, containing his recommendations. He recommends the appointment of a general committee, large enough to provide for its division into sections devoted to special departments of propaganda, and suggests the foregoing name for the committee. He recommends that the chairman of the provincial board of health should be the chairman of the executive committee of the organization. He also recommends that the government provide the money necessary to carry on this work, and that aid should be secured from the Ottawa government. A compulsory course is to be made for medical students in the venereal diseases. He says that salvarsan is a product protected by a German patent. In Canada only two licenses to manufacture it have been granted, and 5 per cent. of the gross sales have been reserved, presumably for the ultimate benefit of the German owners. Only one license has made any progress in Canada in producing it, although the licenses were granted in 1915. The patent commissioners had refused to allow the Ontario Board of Health to manufacture it. He thought this refusal was a national mistake, unless the federal government intended to undertake its production on a large scale.

GENERAL

Base Hospitals Discontinued.—The base hospital at Camp Custer, Mich., and the one at Travis, Texas, have been discontinued and will hereafter be operated as camp hospitals.——No overseas patients will hereafter be sent to Camp Doniphan, Okla.

Flight Surgeons Meet.—Members of the Medical Department of the Air Service of the Army who compose the Flight Surgeons Association met in Dallas, Texas, March 24 to 26. Dr. John O. McReynolds, Dallas, is president of the association and among those who are expected to be present are George H. Crabtree and Albert E. Truby, Cols., M. C., U. S. Army, chief medical executive officer and chief of the air service, respectively.

FOREIGN

Cholera and Influenza in Japan.—It is reported that epidemics of cholera and influenza are prevailing in Japan.

The Schwabacher Prize.—The Schwabacher prize of 20,000 marks was recently divided between Professors Rubner and Zuntz, both of Berlin, for their work on diet in war time.

Reception to American Physicians in London.—A reception was given to 100 American Army medical officers in London, March 19. These officers had arrived in London to take up postgraduate work in England. Sir Humphrey D. Rolleston, president of the Royal Society of Medicine, acted as toastmaster and among the other speakers were Sir Rickman J. Godlee, president of the Royal College of Surgeons; Sir Norman Moore, president of the Royal College of Physicians, and Sir William Arbuthnot Lane.

Some Vital Statistics in Germany, 1914-1917.—J. Schwalbe in a signed editorial in the *Deutsche med. Wochenschrift*, Dec. 12, 1918, states that the mortality from tuberculosis in Germany has increased from 15.7 to 31.7 per ten thousand inhabitants. In 380 towns of over 15,000 inhabitants, the deaths in 1918 from tuberculosis total 43,320 above the figure for 1913. In Berlin the average death rate per month among women has increased from 1,907 in Oct., 1915, to 3,136; the deaths from phthisis, from 205 to 1,752.

Women Decorated by the French Government.—Dr. M. Louise Hurrell, Rochester, N. Y., director of American Women's Hospital No. 1, Luzancy, France, and three of her staff, Mrs. Lenoire-Lehman, purchasing agent and interpreter, and Miss Pettengill and Miss Whitaker, nurses, were decorated by the French government for stamping out the typhoid epidemic in certain cantons of Seine-et-Marne and Aisne.——Dr. Cora H. M. Allen, Heron Lake, Minn., and Eva C. Reed, San Francisco, members of the American Women's Hospital, were also decorated for like service.

Red Cross Hospital in Serbia.—The American Red Cross Hospital established at Monastir, Serbia, under the care of Dr. Regina F. Keyes, Buffalo, is the American Women's Hospital of the American Red Cross and was located until recently in Vodena, Greece. The American Women's Hospitals Organization, by the War Service Committee of the Medical Women's National Association, has given $25,000 for the maintenance of this hospital. Dr. Keyes has been abroad since November 17, and has worked constantly without vacation or change of any kind, operating three times a week, seeing daily between sixty or seventy dispensary patients, and visiting the families of 3,000 refugees.

Deaths in the Profession Abroad.—Dr. **E. Rossoni**, until recently professor of medical pathology at the University of Rome, aged 71.——Dr. **P. Tria**, director of the municipal hospital at Tripoli, member of the editorial staff of the *Riforma Medica*, and formerly lecturer on clinical medicine at Naples, aged 34.——Dr. **Adolf Schmidt**, professor of internal medicine at the University of Halle, a pioneer in the study of diagnostic methods in intestinal disease, author of numerous works on the subject, aged 54.——Dr. **M. Dalmau**, of Barcelona, the first to discover the existence of icterohemorrhagic spirochetosis in Spain. He had not long returned from a graduate course of training in biologic chemistry and bacteriology in this country on a traveling scholarship provided by the Spanish Junta de Ampliacion de Estudios.——The *Nederlandsch Tijdschrift* reports further the deaths of Dr. **E. v. Herczel**, professor of surgery at the University of Budapest; Dr. **K. H. v. Bardeleben**, the anatomist, professor of anatomy at the University of Jena and author of a long series of works on anatomy, spermatology and evolution, aged 69; and Dr. **R. Kobert**, professor of pharmacology, physiologic chemistry and the history of medicine at the University of Rostock, an authority on materia medica and physiologic chemistry, intoxications, etc., aged 65.

BUENOS AIRES LETTER

Buenos Aires, Feb. 10, 1919.

Death of Professor Piñero

The professor of physiology of the Facultad de Medicina of the Univeristy of Buenos Aires, Dr. H. G. Piñero, died recently at Mar del Plata.

Headquarters for Public Health Work in Catamarca

The Departamento Nacional de Higiene has recently inaugurated a regional sanitary station in Catamarca, designed principally to combat malaria in that part of the country.

The Hospitals of Buenos Aires

The appropriations for the municipal hospitals of Buenos Aires were scanty even before the war, but they are entirely inadequate now that the prices of drugs and provisions have increased so considerably. The municipal authorities appear to appreciate this, and in their discussions seem to be inclined to enlarge the appropriations.

Regulation of Prostitution

The Socialist member of the city council, Dr. Jimenez, has proposed that regulation of prostitution be abandoned. He argues that the present measures for regulation in reality amount to a legalized slavery, and that the medical oversight is illusory, as 90 per cent. of the persons with venereal disease who are given treatment in public institutions acquired the disease in houses given official inspection. He advocates the creation of ten night dispensaries for giving aid to persons with venereal disease.

Secularization of the Hospitals

In the hospitals of Buenos Aires, religious sisterhoods perform certain administrative functions or serve as nurses The Socialist members of the city council have proposed the secularization of the hospitals and ask the suppression of religious propaganda and the doing away with the Roman catholic chaplains. The clergy of any sect could be summoned as is the rule at present.

Progress of Public Health at Buenos Aires

According to the data compiled by Dr. Coni, 69,272 persons have died from pulmonary tuberculosis at Buenos Aires in the last fifty years. The mortality, which was 27.2 per ten thousand in the second decade, dropped to 17.4 per ten thousand in the last decade.

Smallpox has disappeared completely from the city, since the vigorous campaign instituted by Dr. Penna in 1910. Compulsory vaccination stamped the disease out entirely.

Between 1887 and 1890 diphtheria was responsible for half the mortality. In the last five decades the mortality from it has been 10.3, 10.9, 11.9, 1.7 and 1.6.

Typhoid fever was endemic here until sanitary measures were introduced. Since then it has appeared in epidemic form at times, but is growing less frequent each year. The general mortality from all other infectious diseases has declined by slow degrees with the progress in public hygiene.

LONDON LETTER

London, March 5, 1919.

The Ministry of Health

Dr. Addison, president of the Local Government Board, has introduced the expected Ministry of Health bill. He said that during the last four years we had lost about 700,000 of our race in the war. During the months of October, November and December last, there was as high an average mortality per month from influenza alone as the average monthly mortality during the war from causes connected with the war. Those who were lost were largely people in the prime of life. There was no doubt that in this matter our practice was far behind our knowledge. We had in the elementary schools an army of children physically defective. What a source of national weakness they were was revealed during the war when hundreds of thousands were unable to pass even the modest standard of physical fitness that the army required. At present a large number of different departments and about 1,800 local authorities deal with public health. Steps must be taken to unify control and get common direction. This country ran the risk of the introduction into it on demobilization of a number of diseases, some of them of a very dangerous kind, from which it had hitherto, or for many years past, been free. Large numbers of soldiers had been affected by dysentery, malaria and other diseases, and an endeavor was being made by joint action of the departments—the War Office, the Admiralty, the Air Ministry, and the Local Government Board—to take steps in common, as far as that was possible, to prevent the introduction and spread of various tropical and other diseases. In the proposed reform there would be two stages, first, to bring together the government's departments concerned in health—the Local Government Board, the insurance commissioners, the board of education and the privy council. This gave the central authority which controlled all the general services of the country, particularly those that related to infancy and maternity. At a later stage powers of control with respect to malnutrition and the ministry of pensions in regard to disabled sailors and soldiers would be taken over. This was not done now because the first amalgamation was a quite big enough undertaking. The ministry of health does not take over the Central Medical Research Committee, which has done such excellent work during the war. This is placed in a detached and independent position under the privy council and will be as wide in its operations as the empire. An important change is the separation of the treatment of sickness from all relations with the poor law. Sickness in the future will be dealt with as a whole from the point of view of the nation and not in relation to destitution. The minister of health will have very wide powers dealing not only with medical services but with preventive services. Thus housing will be in his charge. There will be a wide extension of facilities in connection with nursing, midwifery, diagnosis, hospitals, etc. At present nobody suffered more than the poorly paid classes. Voluntary hospitals looked out for the poor, and there was always a long waiting list. But the poor middle classes cannot afford the fees of the great expert and they do not want to be recipients of charity. Beyond and above any extension of remedial service, prevention is what the ministry must aim at.

A Medical Trade Union

As stated in a previous letter to The Journal, the projected ministry of health has aroused considerable apprehension in the profession, as it is expected to involve further state control and perhaps the introduction of whole-time medical service. The experience of the national insurance act is considered anything but assuring, but the critics of the government differ widely among themselves. The profession is divided into at least three factions — the panel physicians, who have formed themselves into a trade union (the Medico-Political Union); the National Medical Union, which is and always has been bitterly opposed to the insurance act, and the British Medical Association, which endeavors to protect the interests of the profession as a whole but satisfies neither of the two former bodies, who are extremists. The futile attempt to organize the whole profession by a meeting in London called together by the National Medical Union has already been described. It broke up in confusion when the proposal in favor of a trade union, brought forward by members of the Medico-Political Union, was declared lost. The Medico-Political Union has now retorted by calling another mass meeting of the profession to discuss the following resolution: "That in view of the far-reaching changes inevitable in the medical services of this country consequent on the coming Ministry of Health, it is essential that the profession should be solidly and democratically organized on a trade union basis to enable it to negotiate effectively with the government in the interests of the community, no less than those of the profession." About 300 physicians attended. The chairman said that the meeting had been arranged because of the changes which were foreshadowed by the ministry of health bill, which made it imperatively necessary that every branch of the profession should be able to gain a hearing for itself when the provisions of that measure came to be discussed. Panel practitioners would remember what took place seven years ago. The question for them to consider was whether they were any better prepared today to meet the changes that were taking place in their life and work. He was afraid they were not. They had a hope now that they would be able to regain their professional dignity and independence. It had never been their object to strike against sick persons; but, nevertheless, the worm might eventually have to turn, and they must keep an open mind on that subject. In the discussion, the main argument was the success with which trade unions dealt with the government as compared with the failure of the present medical organizations, and the audience showed itself strongly favorable to this view. The opposition was not strong. The main arguments used were that the profession as a whole would never accept trade unionism, and therefore a trade union would further divide it. An appeal to remember the dignity of the profession, and that on those present had fallen the mantles of Harvey and Jenner, fell on deaf ears. An amendment going farther than the resolution: That the trade union be affiliated to the labor party and trade union congress was moved. It was contended that it would be a great advantage to have the whole weight of the trade union movement behind any demand. Against the amendment was urged the fact that the Medico-Political Union consisted of physicians of all political views and that to many the labor party was anathema. The amendment was rejected by an overwhelming majority. The original resolution was carried by 207 against 30. The Medico-Political Union regards the result with great satisfaction, but it must be remembered that all of the physicians in the metropolitan area numbering about 7,000 were invited by a postcard stating the object of the meeting. Probably a higher proportion of the members of the union and of others in favor of the project attended than of those opposed to it. Hence the voting cannot be taken as representative of the profession.

The Influenza Epidemic

Influenza shows some signs of abating in certain areas in London. In North Yorkshire, however, it is on the increase. In Durham County all the elementary schools are closed for three weeks, and whole families are stricken. In Leeds all the elementary schools have been closed. In Edinburgh during the week, 316 deaths occurred, equal to 48.6 per thousand of the population, the highest figure ever reached until the week before last, when an identical number was recorded. These high rates are largely due to the influenza epidemic. The disease is rife in Dublin, and the death rate has risen steadily. A special meeting of the corporation has been called with the object of making it compulsorily notifiable. The medical staffs of the hospitals advised the closing of all schools, theaters, picture houses and public libraries. The epidemic is spreading all over Ireland. The Local Government Board has published a memorandum advising the public not to make a general use of face masks during a period of influenza prevalence. Face masks, however, should be used as much as possible by those who attend on the sick. Although no form of inoculation can be guaranteed to secure immunity, the board says there need be no hesitation in accepting inoculation when it is administered under competent medical advice.

PARIS LETTER

Paris, Feb. 27, 1919.

Vital Statistics of France

The publication of annual or semiannual vital statistics reports was suspended in France during the war. All or at least part of eleven départements were invaded by the enemy, therefore, detailed information on these matters was not available. The ministère du travail (labor) has published in the *Journal officiel* the official statistics for 1915, 1916 and 1917 of seventy-seven départements, and the figures for 1913 are given for purposes of comparison. Although these data are by no means complete, not including all of the country for 1913, they suffice to elucidate the enormous loss in population resulting from the war, and the demographic consequences which follow in the wake of these happenings.

For the seventy-seven départements concerned, the number of births and deaths was as follows:

	Births	*Deaths*
1913	604,811	587,445
1914	594,222	647,549
1915	387,806	655,146
1916	315,087	607,742
1917	343,310	613,148

These statistics show that while in 1913 the number of births exceeded the number of deaths by 17,366, the deaths in 1917 exceeded the births by 269,838. In these seventy-seven départements alone, therefore, the deaths were in excess of 883,160 dating from the beginning of the war to the end of 1917.

It must be noted that these statistics do not include the eleven invaded départements in which war was waged for fifty-two months and in which the losses caused by the war were not counted, but which officially have been stated as being 1,400,000 men.

Deaths

The death is announced of Dr. Henri Henrot, aged 85 years, a former mayor of Reims, vice president of the Conseil supérieur de l'Assistance Publique and corresponding member of the *Académie de médecine.*

Dr. Charles Bonnet, vice president of the Association des médecins légistes, is dead, aged 47 years. Soon after the beginning of the war he placed at the disposition of the Allies the Maison de santé in Paris, of which he was director. This institution became the Canadian hospital and then the hôpital de l'Ecosse.

Dr. *Hippolyte Morestin,* associate professor in the Paris medical faculty, surgeon of the hôpital Tenon and the hôpital militaire du Val-de-Grâce, died recently, aged 48 years. He was born at Fort de France, Martinique, and became a hospital intern when only 19 years of age, a most exceptional occurrence. Although it was known for a long time that he was a bold and masterly operator, his gifts *did not* receive general acclaim until after he gave his services to his country. He worked at Val-de-Grâce, specializing in head and face wounds and prosthetic apparatus, and his results have commanded attention and admiration everywhere. His patience was inexhaustible, therefore he succeeded often in reconstructing the face and rendering existence bearable to many horribly disfigured soldiers.

Dr. Henry Barnsby, professor of clinical surgery in the Tours medical faculty, recently died there, aged 49 years.

Dr. André Chantemesse, professor of hygiene in the Paris medical faculty, died from influenza, aged 68 years. Born at Puy, Oct. 13, 1851, Chantemesse had a particularly rapid career. He became hospital intern in 1880; hospital physician in 1885; agrégé in 1889, and professor of hygiene in the Paris medical faculty in 1898. In 1901 he became a member of the Académie de médecine, section of public hygiene and forensic medicine, and in 1903 he was named inspector general of the Services sanitaires. He was a student of Pasteur, and was one of the first teachers of bacteriology. His researches were made along the lines of the application of bacteriology to hygiene. In March, 1897, in collaboration with Dr. Fernand Widal, Chantemesse discovered the typhoid bacillus in the water of a *borne fontaine* in the Ménilmontant quarter of Paris. Having succeeded in culturing the germ, he prepared an antityphoid serum, which was of great value during the war.

Among his publications may be mentioned his work on typhoid fever, flies and cholera, mosquitoes and yellow fever, written in collaboration with Dr. Borel, and "Frontières et prophylaxis."

Sanatorium de Bligny

The American Red Cross will assume the construction and maintenance of a new pavilion at the Bligny sanatorium (département de Seine-et-Oise). Two hundred tuberculous soldiers will be hospitalized there. At the opening ceremonies, Dr. Louis Mourier, undersecretary of state for the Service de santé militaire, paid tribute to the excellent services rendered by this sanatorium both before and during the war. He extended hearty thanks to our allies for the charitable aid given our sick soldiers. When the sanatorium will no longer be needed for military purposes, it will be at the disposal of the authorities of Paris and the vicinity for use as a hospital. A cure was obtained *in 67* per cent. of the cases treated.

Marriages

Roscoe Frederick Mauser, Lieut., M. C., U. S. Army, Fountain Springs, Pa., to Miss Jean Morrissey of Ashland, Pa., at Chattaroux, France, March 6.

Frank Nathaniel Evans, Lieut., M. C., U. S. Army, Springfield, Ill., to Miss Gertrude Maw of Essex, England, March 12.

Kenneth E. Lowman, Asst. Surg., Lieut., U. S. Navy, to Mlle. Myrtille Adele Fautrat, at Brest, France, January 11.

Dwight Henderson Murray, Syracuse, N. Y., to Miss Elizabeth Fletcher Mann, at Lyons, N. Y., March 22.

William H. Heinzmann to Mrs. Cordelia Clopton Hewlett, both of San Francisco, at San Jose, Calif., March 9.

Robert Fischelis, Philadelphia, to Miss Juanita C. Deer of Chicago, February 20.

Mark Jampolis to Miss Janet Hill McKenna, both of Chicago, March 1.

Deaths

Samuel Carrol Gibson, Reno, Nev.; Missouri Medical College, St. Louis, 1879; aged 61; at one time a member of the Nevada State Medical Association; superintendent of the Nevada State Hospital for Mental Diseases, Reno, from 1904 to 1911; physician of Washoe County; president of the Nevada State Board of Health since 1899; chief surgeon of the Nevada, California and Oregon Railroad since 1900; a director in the Farmers' and Merchants' National Bank, Reno; died in a hospital in San Francisco, March 11.

William Clarence Gates ⊕ Capt., M. C., U. S. Army, Bucyrus, Ohio; University of Michigan, Ann Arbor 1890; aged 50; for several years chief surgeon of the Calumet and Hecla Mining Company, Calumet, Mich.; founder of the Crawford Hospital, Bucyrus; who entered the military service, April 5, 1917, and was on duty at Camp Sherman, Chillicothe, Ohio, and then was sent overseas, and had been on duty at the base hospital in Vichy, France, for six months; died in that institution, February 21, from lobar pneumonia.

Abner Hugh Cook ⊕ Lieut., M. C., U. S. Army, Hot Springs, Ark.; Tulane University, New Orleans, 1910; aged 32; a specialist in internal medicine; on duty at Fort Oglethorpe, Ga., and later at Camp Sherman, Chillicothe, Ohio; formerly major and surgeon of the Fourth Infantry, Ark. N. G.; who was honorably discharged from the United States service, Dec. 17, 1918; died at his home, March 10, from pneumonia.

John Thomas Scott ⊕ Orrville, Ind.; Kentucky School of Medicine, Louisville, 1886; aged 55; secretary of the Stafford County (Kan.) Medical Society; formerly of Indianapolis; professor of obstetrics in the Central College of Physicians and Surgeons, Indianapolis, and consultant in obstetrics in the Indianapolis City Hospital and Dispensary; died at his home in Orrville, February 18, from pneumonia.

Alexander P. Fitch, Crawfordsville, Ind.; Washington University, Baltimore, 1871; aged 70; a member of the Indiana State Medical Association; formerly secretary of the Boone County (Ind.) Board of Health; assistant supreme medical examiner of the Order of Ben Hur; 1886 to 1889 in the United States Indian Service in South Dakota; died at his home, December 6, from angina pectoris.

George Amos Harman, Lancaster, Ohio; Medical College of Ohio, Cincinnati, 1871; Bellevue Hospital Medical College, 1874; aged 77; physician to the Ohio State Reform School, Lancaster, from 1874 to 1878; surgeon to the Sixth Battalion, Ohio State Militia, in 1875 and 1876; medical director of the Department of Ohio, G. A. R., in 1877 and 1888; died at his home, March 4, from heart disease.

William Robert Arlington Carley, Brooklyn; Bellevue Hospital Medical College, 1888; aged 55; a member of the Medical Society of the State of New York; a member of the staff of Bethany Deaconess, Bushwick Central, Long Island College, and Brooklyn hospitals; died in Long Island College Hospital, March 11, a week after an operation for the removal of an enlarged gland.

Osee Wallace Hoffman, Denver; Laura Woman's Medical College, Cincinnati, 1897; aged 43; assistant clinical professor of ophthalmology in the Denver and Gross College of Medicine, and chief of the eye and ear department of the Women's Free Dispensary, Denver; died in Mercy Hospital, Denver, March 5, from tuberculosis.

Alonzo H. Mackey, Gorin, Mo.; College of Physicians and Surgeons, Keokuk, Iowa, 1878; aged 60; a member of the Missouri State Medical Association; while driving in his automobile, March 7, over a grade crossing of the Sante Fe System, near Gorin, was struck by a freight train and instantly killed.

Jarvis Mitchell Howes ⊕ Sellersburg, Ind.; Kentucky University, Louisville, 1893; aged 57; for many years a druggist at Jeffersonville; while driving his automobile over a grade crossing of the Baltimore and Southwestern Railway, near Prather, March 5, was struck by a passenger train and almost instantly killed.

Charles W. Birdsall, Weavers, W. Va.; College of Physicians and Surgeons, Baltimore, 1885; aged 67; at one time a member of the Medical and Chirurgical Faculty of Maryland; died in the Davis Memorial Hospital, Elkins, W. Va., February 11, from pneumonia following influenza.

William Burt, Paris, Ont.; University of Toronto, Ont., 1870; aged 70; president of the Ontario Medical Association in 1905; and a member of the Ontario Board of Medical Examiners from 1889 to 1892; died at his home March 14, from pulmonary tuberculosis.

Wilford Wayne Martin ⊕ Lieut., M. C., U. S. Army, Kirksville, Mo.; Eclectic Medical University, Kansas City, Mo., *1903*; aged 41; on duty with the American Expeditionary Forces at Rouen, France; was thrown from his horse and instantly killed, December 4.

Homer Earl Gordon, Lansing, Mich.; Saginaw Valley Medical College, Saginaw, Mich., 1898; aged 64; at one time a member of the Michigan State Medical Society; for two years superintendent of schools of Tuscola County, Mich.; died at his home, March 4.

Alpha Mason Whiton, U. S. Indian Service, Fort Totten, N. D.; Hahnemann Medical College, Philadelphia, 1881; aged 61; on duty at the Indian School and Hospital at Fort Totten; died at that place, February 24, from pneumonia and angina pectoris.

Winfield March White ⊕ Lieut., M. C., U. S. Army, Sioux City, Iowa; State University of Iowa, Iowa City, 1912; aged 29; on duty with the American Expeditionary Forces in France; was killed in action, November 4, at Bazancourt Farm, France.

Harry Augustus Scheppach ⊕ Lieut., M. C., U. S. Army, Newark, N. J.; Bellevue Hospital Medical College, 1898; aged 43; on duty at the Yale Army Laboratory School, New Haven, Conn.; died in New Haven, January 29, from typhoid fever.

James H. Carter, Seymour, Ind.; University of Louisville, Ky., 1879; aged 70; at one time a member of the Indiana State Medical Association; secretary of the Seymour Board of Health; died at his home, March 10, from cerebral hemorrhage.

William James Bulgar ⊕ Oswego, N. Y.; Long Island College Hospital, Brooklyn, 1882; aged 61; consulting physician to the Oswego Hospital; collector of the port for four years; mayor of Oswego in 1893; died at his home, March 3.

John L. Caldwell, Waverly, Ohio; Cincinnati College of Medicine and Surgery, 1874; aged 75; a member of the Ohio State Medical Association; physician to the Pike County Children's Home; died at his home, March 7.

Arthur Lee Cunningham ⊕ Oakland, Calif.; Hahnemann Medical College, Pa., 1890; aged 52; chief surgeon to Fabiola Hospital, Oakland; at one time a member of the Oakland Board of Health; died at his home, March 3.

Ellenwood Bunker Coleman, Nantucket, Mass.; Chicago Homeopathic Medical College, 1888; aged 56; for three years representative from Nantucket in the state legislature; died at his home, February 27, from angina pectoris.

Ellsworth Hazen Noble ⊕ Elmira, N. Y.; New York Homeopathic Medical College, New York City, 1890; aged 53; a specialist on diseases of the eye, ear, nose and throat; died at his home, March 6, from acute gastritis.

John Vinson Brann, Knoxville, Iowa; Medical College of Ohio, Cincinnati, 1881; aged 65; local surgeon of the Rock Island System; at one time a member of the Iowa State Medical Society; died at his home, March 8.

Alexander Rhea Kuykendall, Dayton, Texas; Missouri Medical College, St. Louis, 1885; aged 59; a member of the State Medical Association of Texas; died in a sanatorium in Waco, Texas, February 17, from paresis.

Solomon Charles Mish, San Francisco; Kentucky School of Medicine, Louisville, 1892; aged 50; formerly professor of therapeutics in the West Coast Medical College in San *Francisco; died at his home, March 2.*

Charles Haight Holcombe ⊕ Lieut., M. C., U. S. Army, Trenton, N. J.; Jefferson Medical College, 1901; aged 51; a specialist in roentgenology; for several years a druggist of Trenton; died at his home, March 5.

Sarah Lamb Cushing, Lockport, N. Y.; Starling Medical College, Columbus, Ohio, 1859; aged 100; one of the first women to take up medical practice in the United States; died at her home, March 12.

William Crooks Hertzler ⊕ Toledo, Ohio; Jefferson Medical College, 1894; aged 54; died in his office, March 7, from an overdose of an opiate taken to relieve pain, following an operation on his nose.

Herman Vedder Mynderse ⊕ Schenectady and Scotia, N. Y.; Albany (N. Y.) Medical College, 1889; aged 57; attending physician to the Ellis Hospital Schenectady; died at his home, March 5.

⊕ Indicates "Fellow" of the American Medical Association.

Charles Olaf H. Nordwall ⊕ Rockford, Ill.; John A. Creighton Medical College, Omaha, 1906; aged 47; died in the Michael Reese Hospital, Chicago, March 7, from chronic interstitial nephritis.

Charles W. Hedrick, Willard, Ohio; Columbus (Ohio) Medical College, 1883; aged 55; for thirty-five years medical examiner for the Baltimore and Ohio System; died at his home, March 7.

Walton W. French, Chattanooga, Tenn.; New York Homeopathic Medical College, 1875; aged 83; a veteran of the Civil War; died at his home, February 24, from cancer of the face and neck.

Henry Crawford Walker, Hockessin, Del.; Jefferson Medical College, 1891; aged 64; for several years a druggist of Philadelphia; died at his home, March 2, from heart disease.

Frederick B. Palmer, Atlanta, Ga.; Southern Medical College, Atlanta, 1883; aged 80; a Confederate veteran; for many years a pharmacist of Atlanta; died at his home, March 13.

Henry Peffer, Summit, N. J.; New York University, New York City, 1883; aged 71; formerly a member of the staff of the Manhattan State Hospital; died at his home, March 8.

William Pugh Haynes, Clarksville, Tenn.; formerly of Oakwood, Tenn.; University of Tennessee, Nashville, 1894; aged 60; died at his home, February 26, from pneumonia.

George Loring Porter ⊕ Bridgeport, Conn.; Jefferson Medical College, 1862; aged 80; surgeon of U. S. Volunteers during the Civil War; died, February 17, in Stuart, Fla.

Robert Clemens Smedley, Denver; Denver College of Medicine, 1900; aged 47; at one time a member of the Colorado State Medical Society; died at his home, March 1.

Wiley B. Finney, Pelham, Ga.; University of Georgia, Augusta, 1891; aged 59; died at the home of his daughter near Ty Ty, Ga., February 4, from pneumonia.

John Henry Myers, Lewistown, Pa.; Baltimore Medical College, 1883; aged 78; a veteran of the Civil War; died at his home, March 6, from cerebral hemorrhage.

Joseph Levi Hogan ⊕ Oregon, Mo.; Ensworth Medical College, St. Joseph, Mo., 1909; aged 35; died in a hospital in St. Joseph, March 12, after a surgical operation.

John Manson, Lincoln, Calif.; University of Victoria College, Corburg, Ont., 1866; aged 80; a resident of California since 1869; died at his home, February 28.

Everett White ⊕ East Lynn, Mass.; College of Physicians and Surgeons, Baltimore, 1897; aged 48; died in Roxbury, Boston, February 27, from tuberculosis.

George W. Tepe ⊕ Evansville, Ind.; Hospital College of Medicine, Louisville, Ky., 1893; aged 47; died in Evansville, December 8, from surgical shock.

Jacob May, Bridgeport, Conn.; Rush Medical College, 1876; aged 68; a member of the Connecticut State Medical Society; died at his home, February 23.

Raymond B. Houston ⊕ Seneca, Kan.; Central Medical College of St. Joseph, Mo., 1905; aged 36; died at his home, February 10, from pneumonia.

Harrison M. Bennett, Takoma Park, Md., and Washington, D. C.; Howard University, Washington, D. C., 1882; aged 75; died at his home, February 26.

Ernest Freeman Norcross, Boston; Boston University School of Medicine, 1892; aged 67; died at his home, Dorchester, Boston, March 3.

Gustav C. Fichtner, San Francisco; Hahnemann Medical College of the Pacific, San Francisco, 1887; aged 71; died at his home, March 12.

John C. Tillman, Sidney, Ohio; Medical College of Ohio, Cincinnati, 1877; aged 64; died in his apartment, March 2, from heart disease.

Robert Sidney Hendry, Taylor's Creek, Ga.; University of Georgia, Augusta, 1899; aged 49; died in a hospital in Savannah, February 10.

William A. Hubbard, Cedar Rapids, Iowa; Hahnemann Medical College, Chicago, 1885; aged 64; died at Battle Creek, Mich., March 11.

Edward Rawlins Tarry, Omaha; University of Maryland, Baltimore, 1893; aged 46; died at his home, March 7, from pneumonia.

Basil M. Webster, Council Bluffs, Iowa; Rush Medical College, 1869; aged 71; died at his home, March 6, from heart disease.

Thompson R. Brady, Wabash, Ind.; Rush Medical College, 1869; aged 75; died at his home, March 10.

Correspondence

CASE OF LETHARGIC ENCEPHALITIS

To the Editor:—With reference to the editorial in The Journal, March 15, on lethargic encephalitis, a brief report of a recent case under my observation may be of interest:

A woman, aged 40, married, mother of two children, in good health, was first seen by me, February 15, soon after she began to experience profound and constant drowsiness. Both levator palpebrae muscles were partially paralyzed, so that both lids remained half closed. Pulse, respiration, temperature and pupils were normal. In the earlier part of the attack, slight elevation of temperature—from 99 to 100—was occasionally noted. There was no photophobia and no pain. The urine was normal. There was no coma. The patient was easily aroused, but on one or two occasions she manifested temporary confusion of ideas.

Neither the patient nor any member of her immediate family has had influenza. A sister and her husband, living in an adjoining house, both had influenza, one early in October last and the other three months later, and influenza had prevailed here for five months preceding her illness.

No appreciable cause can be assigned for this attack, which continued, in gradually decreasing intensity, for one month, ending in recovery. During her confinement, she gained several pounds in weight.

Treatment consisted of rest in bed, a liberal diet, repeated cathartics, caffein freely, some quinin and, later, moderate doses of strychnin.

James B. Baird, M.D., Atlanta, Ga.

STANDARDIZATION OF DEGREES IN PUBLIC HEALTH

To the Editor:—In view of the importance of arriving at some measure of standardization for the various degrees and certificates offered in the field of public health, Yale University invited a group of representatives from neighboring universities to confer in regard to the matter at New Haven, Feb. 28, 1919. Johns Hopkins University was represented by Dr. W. H. Welch, the Massachusetts Institute of Technology by Prof. W. T. Sedgwick, Harvard University by Dr. M. J. Rosenau, New York University by Dr. W. H. Park, and the University of Pennsylvania by Dr. H. F. Smyth, while Yale University was represented by a special committee from the Graduate School, including Profs. S. E. Barney, L. B. Mendel, L. F. Rettger, M. C. Winternitz and C.-E. A. Winslow.

After very full discussion of the various points involved, the following resolutions were unanimously adopted:

1. That the degree of Doctor of Public Health (for which the abbreviation should be Dr.P.H.) for graduates in medicine should normally be awarded after two years of work done under academic direction, of which one year at least should be in residence and that the requirements for the degree should include class work, practical field work, and an essay based on individual study of a particular problem.

2. That the degree of Doctor of Philosophy or Doctor of Science in Public Health or Hygiene should be conferred on students who hold the bachelor's degree from a college or technical school of recognized standing, and have satisfactorily completed not less than three years of graduate study. It is understood that this degree is based on the fundamental sciences associated with hygiene and public health, including a knowledge of physics, chemistry, general biology, anatomy, physiology, physiologic chemistry, pathology and bacteriology, in addition to the thesis and other usual requirements for the Ph.D. or Sc.D. degree.

3. That the Certificate in Public Health should be granted for not less than one academic year of work to those who have received a bachelor's degree from a recognized college or technical school, or have satisfactorily completed two years of work in a recognized medical school, provided they have previously pursued satisfactory courses in physics, chemistry, general biology and general bacteriology.

tions are luted with melted petrolatum or paraffin, a drop of immersion oil is placed on the dark field condenser, and the slide is placed on it. Another drop of immersion oil is placed on the cover glass, and the oil immersion lens brought in contact with it. Details of the technic will vary with different operators. For a full dicussion of dark ground illumination, A. E. Wright's "Principles of Microscopy," New York, the Macmillan Company, Chapter XIV, may be consulted.

LITERATURE ON PYORRHEA ALVEOLARIS

To the Editor:—Will you kindly recommend a recent book on pyorrhea? I prefer a book that treats this subject exclusively.

Frederick Booth, LaPorte, Ind.

Answer.—The following books may be consulted:

Bass and Johns: Pyorrhea Alveolaris, Philadelphia, W. B. Saunders Company, $2.50.

Hecker: Pyorrhea Alveolaris, St. Louis, The C. V. Mosby Co., $2.

Talbot, E. D.: Interstitial Gingivitis and Pyorrhea Alveolaris, Toledo, Ransom and Randolph Co., $4.

Book Notices

Manual of Surgical Anatomy. Authorized by the Secretary of War and under the Supervision of the Surgeon-General and Council of National Defense. Prepared under the Direction of the Division of General Surgery in Collaboration with the Divisions of Orthopaedic Surgery, Surgery of the Head, Genito-Urinary Surgery and the Advisory Staff in Surgery in the Office of the Surgeon-General, U. S. Army. Cloth. Pp. 387, with illustrations. 1918.

This manual was prepared for the use of the medical departments of the Army and Navy. As its preparation was essentially a war measure, to use a trite phrase, it was not difficult to obtain the permission of various medical publishers for the reproduction of illustrations that appeared in their publications. The book is divided into four parts covering the divisions of the body, and the subjects have been presented in the following order: (*a*) transparencies or projections showing the deeper structures viewed in their natural positions as though the overlying structures were transparent; (*b*) systematic dissections; (*c*) regional dissections; (*d*) frontal, sagittal and transverse sections, and (*e*) surgical incisions. The international Basle nomenclature is used, and an explanatory index gives the equivalents for these terms. Most of the work was done in the department of anatomy of the University of Illinois. The compilers of the book have borrowed extensively from the best anatomic works available today in all modern languages, using freely those texts under Allied control and, at the same time, many German and Austrian textbooks. There are 327 pages of especially selected illustrations well printed on enamel paper. The result is an almost invaluable anatomic work. The civil sale of the manual is prohibited, its use being restricted to the Army and Navy. This is unfortunate, since the work would undoubtedly be of the greatest service to medical students. It is to be hoped that some arrangement may be made whereby at least several copies may find their way to the anatomic laboratories of our medical schools.

Forced Movements, Tropisms, and Animal Conduct. By Jacques Loeb, M.D., Ph.D., Sc.D., Member of the Rockefeller Institute for Medical Research. Cloth. Price, $2,50 net. Pp. 209, with 42 illustrations. Philadelphia: J. B. Lippincott Company, 1918.

The present volume is the first of a series of monographs on experimental biology to be written by American biologists under the general editorship of Jacques Loeb, T. H. Morgan and W. J. V. Osterhout. It embodies the author's conceptions respecting the nature of animal conduct. As many biologists are aware, animal conduct was explained by this author on the tropism theory some thirty years ago. In the course of years, many extensions have been made to this theory by himself and others. The book gives a brief but clear-cut summary of the entire subject as it stands today.

Not since the appearance of Descartes' treatise on man in the seventeenth century have such purely mechanistic ideas of animal conduct been so openly expressed as in this book. To be sure, Descartes constructed the machinery of the animal body and of man to suit his fancy, and endowed the latter with a soul to regulate its activity. In the last analysis, the machine of Descartes and that of Loeb are essentially the same. Both looked at the body as a whole so constructed that its every movement is the inevitable result of some form of stimulation. The seventeenth century philosopher deduced his conceptions of the body's activity from a consideration of a few anatomic facts and factitious assumptions; the modern experimentalist bases his convictions on a close quantitative study of the reactions of animals to light, galvanic currents, chemicals, heat, etc., to which animals are subjected. In the judgment of Loeb, the conduct of animals, including man, is nothing more nor less than the expression of tropistic reactions. To both the body represents merely a machine so constructed that its responses to a given stimulation are in most instances predictable. And whereas Loeb dispenses with a governing soul, Descartes defended his position in this respect with more wisdom, possibly, than conviction.

The lucid discussion of the various tropistic reactions prepares the ground for a discussion of instinct and memory images in the final two chapters of the book. In the former, dealing with instinct, the importance of sex hormones (particularly) are admitted to modify tropistic reactions. The discussion in the final chapter of memory images from a tropistic point of view is less complete and convincing. Data are lacking, as are methods for obtaining them. Learning, according to the author, presupposes associative memory, whose physical mechanism is again admittedly unknown. Nor is Loeb's position strengthened by stating that the conditioned reflexes or memory images of Pawlow are the cause of the variations and multiplication of possible tropistic reactions. The intangibleness of this memory image, and added special tropism, as a source of forced orientation fails absolutely to convince the verbalist, anthropomorphic author, or scientist; for when Loeb attempts to explain apparent free will of animals and man in the government of their actions by the tropistic effects of memory images, and the modification and inhibition of tropisms by memory images, both mechanists and vitalists will ask for his conceptions as to the physical or chemical nature of these memory images. His hypothesis as to the nature of so-called free will or premeditated acts is scientifically weak because it lacks data. Aside from this, the book contains much on animal conduct and its explanation that ought to be more generally known by biologists, and particularly by psychologists.

Intent and Revocation of License in Abortion Case

(Rodermund v. State (Wis.), 168 N. W. R. 390)

The Supreme Court of Wisconsin, in affirming a judgment of conviction of defendant Rodermund of having used instruments in the treatment of a pregnant woman with intent to procure a miscarriage as denounced by the provisions of Section 4583 of the Wisconsin Statutes, says the defendant insisted that the trial court erred in submitting the question of his guilt or innocence to the jury, and asserted that the evidence did not sustain the charge preferred against him of having used instruments on the person of a pregnant woman with the intent to produce a miscarriage. The defendant testified in substance that he found the woman in process of miscarriage, that he rendered proper medical aid for such condition, that he did nothing to produce a miscarriage, that his treatment of her was for alleviating her serious condition and to protect her life, that he did nothing to prevent publicity of his connection with or treatment of her case aside from what proper professional conduct demanded of him in compliance with her wishes, that all of his professional services were rendered for the purpose of giving her proper medical care, and that he had no intent to do anything to procure a miscarriage. The proper inference from the evidence was necessarily dependent on the credibility and weight which was given to the statements of the various persons who testified. The case was therefore one wherein the jury and the trial court that saw the witnesses on the stand and observed them while testifying could much better ascertain the probative force of the evidence than could be ascertained by a review of the printed record. The facts and circumstances shown were as to their significance, and the inferences to be drawn therefrom as to the defendant's guilt or innocence were peculiarly within the function to be exercised by the triers of fact. The offense charged involved the inquiry: With what intent did the defendant give this woman the treatment he testified to? Such intent was a fact which must be ascertained from a consideration of the circumstances which threw light on the defendant's acts. If he had the felonious intent of producing a miscarriage, then guilt was established though he did not in fact procure a miscarriage.

The circuit court sentenced the defendant by the imposition of a fine and the costs of the action, and, in default of the payment of such fine and costs, committed him to the county jail for a period not to exceed six months. It also adjudged a revocation of the defendant's license to practice medicine and surgery, applying the provision of Section 1435 i of the statutes that:

> . . . If any person licensed or registered by said board shall be convicted of any crime, committed in the course of his professional conduct, the court in which such conviction is had shall in addition to any other punishment imposed pursuant to law revoke said license or certificate.

It was held in *State* v. *Lewis*, 164 Wis. 363, 159 N. W. 746, that the effect of this statute is simply to give, as an incident to such conviction, power to the court in the criminal proceeding to do directly and forthwith what might be done in subsequent civil proceedings. The supreme court is persuaded that this interpretation of the statute is correct, and hence the contention of the defendant that it provides additional criminal punishment and that it constitutes cruel and unusual punishment was without merit. The term "crime," as used in this provision, was manifestly employed to embrace the violation of any penal law of the state, and clearly includes all felonies and misdemeanors under the law of the state committed by the offender in the course of his professional conduct. The terms of the statute leave no room for different interpretation of the word "shall" in the provision that the court on record of conviction "shall" revoke the license or certificate of the person convicted. It is apparent that the legislature intended that a criminal conviction of any such licensed or registered person shall be deemed to be a conclusive test of unfitness to continue further in the practice of his profession, and made it mandatory on the court to revoke such license. This is properly a legislative question.

JOINT SESSION OF THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES AND THE FEDERATION OF STATE MEDICAL BOARDS

(Concluded from page 892)

The Desirability of Changing the Type of Written Examinations

Dr. George Blumer, Dean of Yale University School of Medicine, New Haven, Conn.: To be published in full in The Journal.

Advisability of Combining Examinations of the National Board, State Boards and Medical Schools

Dr. John S. Rodman, Secretary of the National Board of Medical Examiners, Philadelphia: During the past three years the National Board of Medical Examiners has sought to develop an ideal examination for determining the fitness of a candidate to practice medicine. In doing so the board has sought for principles to govern its future action rather than to examine large groups of applicants. As predicted by the founder of the board, the examination is adapted more to the exceptional than to the average applicant.

The board has tried to steer between technicality, on the one hand, and laxity, on the other. It has recognized the necessity of giving an examination sufficiently thorough to be recognized by state examining boards, and yet to make it of so practical a nature that a qualified candidate has a reasonable chance of passing it. Figures will show that the latter aim has been accomplished, since 80 per cent. of those who were qualified to enter the examination have received certificates. The board believes that the state boards' approval is being obtained. The board has endeavored to determine the fitness of a candidate to practice up-to-date medicine, rather than to pass on his special knowledge in any one specialty.

As time goes on, this board may be in a position to offer suggestions in regard to methods of teaching certain subjects.

The dean of one of our medical schools suggests that the examinations of the national board be combined with the final examinations of medical schools, the thought being that the national board's examination might be accepted by the school in lieu of its own final examination. After careful consideration, the board decided that while the plan had many merits, this was hardly the field which the national board had been created to enter. The final examination of a medical school, leading as it does to a degree, must be more or less academic in character, while that of the national board must determine the ability of the candidate, once having received the degree, to apply his knowledge to actual practice. Furthermore, the board requires a year of hospital work as intern after graduation, as a prerequisite to candidature for its examination.

DISCUSSION ON EXAMINATIONS

Dr. John M. Dodson, Chicago: It is extremely important and desirable that there should be some examination which could be taken by the young man entering the profession of medicine, which will insure him for all time the right to practice anywhere in this nation, without the distressing embarrassment of finding himself in middle life or later obliged to move from one state to another and to submit to a technical examination in branches from the study of which he has long been removed, and which acts as an effectual barrier against his transferring to another state.

Those of us who have had to do with administration of medical schools know in many instances of the hardships imposed by our impossible system of state licensure without reciprocity which have been forcibly brought to our minds. One of the worst features of reciprocity agreements has been the ridiculous "I will if you will" attitude of the various boards. About ten years ago, it was discovered that one state had examined one sixth of all physicians who in that year were licensed by reciprocity in the United States. Young men were taking examinations in that state because they were easy to pass, and were then obtaining their licenses by reciprocity in the states where they intended to practice. The other states put a stop to that practice by adopting a rule that no license would be granted by reciprocity to a practitioner of another state until he had practiced at least one year in the state where he secured his original license. The officials of the first board concerned were apparently very wrathful at this and came back with a ruling demanding two years of practice. In that state a young man could not get a license unless he had been practicing for two years in another state. About two months ago a graduate of Rush Medical College was offered a desirable position in a certain state with an industrial concern. He had been in practice about eighteen months. The board of the state to which he wanted to go first had the rule of one year, but it says that "we cannot accept a man unless he has been in practice for two years because the other state requires two years, but if that state will change its rule to one year we will admit this man." The other state stood pat, so the young man could not move to that state. He was willing to take the examination, but no examination was to be held for four months; hence he was debarred from accepting a desirable position because of this ridiculous attitude of a state board. This is one of many instances just as absurd which are working a serious and unjustifiable hardship on physicians.

I do not think we desire universal reciprocity. With the wide divergence of standards in the forty-eight states, we should not gain if we had universal reciprocity. I can see no solution of this difficulty except through some agency like the National Board of Medical Examiners, and its progress in the last two or three years in the direction of better examinations entirely commands my confidence. I hope to see the time when the acceptance of its certificate will be universal in this country, and when the earnest young men desirous of securing licenses can go anywhere at a minimal expense and with little trouble. I hope the board will find it possible to hold three or four simultaneous examinations in different cities, for that will be necessary if the students are to take them.

Dr. B. D. Harison, Detroit: It would be very foolish, when a candidate has a certificate from the National Board of Medical Examiners and goes into a state with the idea of practicing, for members of the state board to put him through the whole formula of passing another examination, when the examination he has already passed is more rigid and far superior to that which is provided by the state. I think other methods might be used in such cases; I am quite sure they can be, so that in effect the certificate of the national board should be recognized in all states. A number of states have already recognized it. I do not think any one would be sufficiently interested in a case of this kind to bring suit against the state board to prevent its recognition. There would be nothing in it for the man who prosecutes; he would not help himself or help anybody else.

The great weakness of the national board is its administration, particularly in the evaluation of credentials. If the board would use open methods of administration I think it would raise the standard to a very large extent. Very few of the state boards at present administer their preliminary requirements. They do not seem to know how. There is more care required in the administration of preliminary credits than in any other administration policy. It is a profession in itself, and there should be uniformity in administrative methods in regard to that. It would do a tremendous amount of good.

I had the privilege of attending the examination of the national board in New York a year ago, and I must say from my experience there that the examination was ideal. I do not know of any examination that is so thorough and yet so fair, and any graduate of a first class medical college should be able to pass this examination.

Dr. Isadore Dyer, New Orleans: The question of cooperation of the national board with the examinations of students graduating from medical schools, examinations for internships, and with state board examinations, is one that for some time in the future probably could not be made practicable. The purposes of the National Board of Medical Examiners should be reviewed. When created, it was intended to offer an examination which would be more or less academic, which should test the exceptionally qualified candidate, and which should certify him, if found qualified, to any one who might be concerned. The board demanded graduation from an acceptable high school; two years of college work which would include the sciences required by the Council on Medical Education in its published requirements; graduation from a Class A school, and an internship in an acceptable hospital. It has not been the board's function to consider any other examination. The board is interested in the general problem of medical education. It has assumed no attitude of leading in the problems which are before this body, but desires to have a part in the consideration of the problems that are arising. The state boards have not yet standardized their own examinations; not all of the states have yet come into the membership of the Federation of State Boards. It would be a presumption on the part of the National Board of Medical Examiners to hold an examination qualifying for a state board unless the initiative in this regard came from that board.

Dr. Thomas McDavitt, St. Paul: I have had the great pleasure of being present at three examinations of the national board, and they impressed me very favorably. It was unfortunate, so far as the national board is concerned, that it could not be legalized by the national government. Could that have been done, every state would have accepted its certificates. I think its examinations are more difficult than any I have ever attended. No state board has an examination that compares with it. Unfortunately our law in Minnesota was so stringent as regards its verbiage that we could not accept the examination of the national board; but we have bills in both houses of the legislature at present providing for an amendment to our law, whereby we shall be enabled to accept the examinations of the national board on the same basis that we accept those of other states in the matter of reciprocity.

W. C. Rucker, Major, M. C., U. S. Army, Newport News, Va.: In examining a man we should bear in mind what we are examining him for. If it is to find out whether he is a scientist, he should be given one type of examination. If it is to find out whether he can treat sick people, you must give him another type of examination. There is one thing however, which he is not examined in, and that is his temperamental fitness to practice medicine. We should determine a man's ability to meet an emergency. Almost any one can examine a patient, go home and read up on the subject, find out what to do and blunder along, but it takes a good man to meet an emergency. The United State Public Health

Service a few years ago undertook to put into practice a test more or less psychologic which would in a measure determine the temperamental fitness of men, and it was surprising to see the number of men who were found unfit.

Dr. James Ewing, New York: I had the opportunity to see some of the examinations conducted by the national board in New York, and I can say that the experience of passing through such an examination is a liberal education in itself. I think this board is doing much toward maintaining and even raising the standard of medical education in this country. Its theoretical conception, its philosophy, is entirely sound. Up to the time of the war in Europe, it is a fact that the medical schools provided a very considerable number of men who entered the other sciences and became prominent in them; but in this country the medical schools did not provide enough men to teach the sciences to medical students. There are few prominent teachers of anatomy in this country who hold medical degrees. Some of them have honorary degrees. The same situation exists with regard to physiology. Medical schools have not provided sufficient men to teach their own students the fundamental sciences of medicine.

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

American Journal of Diseases of Children, Chicago

March, 1919, **17**, No. 3

*Epidemic Influenza in Infants. M. Wollstein and A. Goldbloom, New York City.—p. 165.

*Unusual Case of Aplastic Anemia. L. W. Smith, Boston.—p. 174.

*Relation of Parental Nativity to Infant Mortality in New York State. P. R. Eastman, Albany.—p. 195.

*Simple Method of Modifying Fat Content of Milk for Infant Feeding. A. L. Daniels and H. English, Madison, Wis.—p. 212.

Influenza in Infants.—This paper is based on studies made by Wollstein and Goldbloom at the Babies' Hospital of the City of New York. Of thirty-six children who had bronchopneumonia and influenza, twelve recovered and twenty-four died, a mortality rate of 66.6 per cent. Of the twenty-four fatal cases, eighteen came to necropsy. These eighteen cases showed a variety of pulmonary lesions making a characteristic picture of congestion, edema, general bronchitis, scattered pneumonia lesions differing in age, but involving two or more lobes; subpleural hemorrhages and pleural exudate. Capillary hemorrhages in the other viscera were constant. The influenza bacillus was grown from every case, but not alone. Pneumococcus Type IV was the most frequent bacterium associated with it. During life the sputum contained *B. influenzae* in thirteen of seventeen cases in which it was searched for. This series of pneumonias was far more severe, more extensive and more highly fatal than was any other group of pneumonia cases observed in the hospital over a similar period of time.

Aplastic Anemia.—The clinical history of Smith's case can be summed up briefly as follows: A boy of 6 who had been apparently well up to the time of the present illness, with the exception of measles eight months previously, came into the hospital with a history of only two weeks illness, with no definite symptoms. The clinical picture and the laboratory findings were roughly those of rather a severe secondary anemia, cause unknown. There had been no history of hemorrhage, or of any more recent infection than the measles. He responded temporarily to iron treatment, but soon became more anemic and progressed rapidly downhill to fatal exitus. There were very slight purpuric manifestations, and an unexplained swelling of the face, accompanied by high fever. The blood picture at first suggestive of secondary anemia, became more definitely that of an aplastic anemia. The degree of anemia was extreme—hemoglobin, 40 per cent.; red count, 1,500,000. The differential white count showed a beginning relative lymphocytosis and a drop in the leukocytic proportion; a good deal of poikilocytosis, anisocytosis and polychromatophilia. Three months after the boy was first seen, the red cells numbered 700,000, hemoglobin, 18 per cent.; an obvious relative lymphocytosis. The immediate cause of death was a failing circulation with dilatation of the heart, accompanied by decompensation. The edema of the lungs was partially responsible as well. At the necropsy there was found an extreme marrow aplasia. The malpighian corpuscles in the spleen gave very definite evidence of prolonged toxic action such as is seen especially in diphtheria, or in any of the prolonged febrile diseases. It is frequently concomitant with measles. Smith is convinced that this is, perhaps, the most obvious answer to the whole story—the prolonged toxic action of the toxin of measles, acting in a cumulative sort of fashion, until the marrow became exhausted.

Parental Nativity and Infant Mortality.—The statistics given by Eastman are taken from the records of the New York State Department of Health in which New York City is not included. It is evident that the several causes culminating in the present high mortality of infants are strongly influenced by the customs and racial characteristics of the various peoples inhabiting the state. Among the foreign born, and particularly the Italians and Slavic races, the principal diseases are those here classed as communicable, respiratory and gastro-intestinal. The superior environment and intelligence of the average native woman is reflected in the comparatively low mortality of her babies from these diseases. The fewer deaths from prematurity and congenital defects among children of Italian, Russian, Polish and Austro-Hungarian parents may possibly be accounted for, in part, by the greater vitality and superior constitution of these infants. If this is true, there is the more reason to deplore the excessive mortality incident to them during the later months of infancy, since it would seem that if it were not for the ignorance of the parents, they actually start life with a better chance of survival then do other children. Compared with the foreign born, the death rate from prenatal causes is exceptionally high among the children of native mothers. On the other hand, in a community composed largely of Italians or Slavs, the principal causes to be combated are those arising from poverty, ignorance, overcrowding and imperfect sanitation.

Modifying Fat Content of Milk.—The method used by Daniels and English consists in allowing the milk to stand on ice until the cream line is distinct—about ten or twelve hours. The cream is then carefully removed, so that as little mixing as possible takes place. For this purpose a Walker-Gordon dipper with a removable bottom has been found most convenient. In order to obtain milk containing 2 per cent. fat, 2 ounces, or 54 c.c., of the removed cream should be added to 24 ounces of the skimmed milk; for a 3 per cent. milk 4 ounces, or 108 c.c., should be returned to 24 ounces of the skimmed milk, and for a 4 per cent. milk 6 ounces, or 162 c.c., should be added. The length of time the milk has stood after boiling is of considerable importance in securing good results with the method, for milk which has stood a too short period contains a varying amount of fat in the skimmed portion.

*Artificial Pneumothorax in Tuberculous Pneumonia. H. E. Gammons, Deerwood, Minn.—p. 501.

Induced Pneumothorax Treatment of Pulmonary Tuberculosis.—Morris reports on this treatment as used in the Cook County Tuberculosis Hospital in 202 cases. They have used only the Murphy outfit, with some changes necessitated by the use of atmospheric air instead of nitrogen gas. Instead of using the atmosphere in the room, a long rubber tube is connected at one end with the intake valve of an ordinary aspirating pump and at the other with a metallic bathroom spray loosely fitted with sterile cotton. This end is placed in the outside air, which is then pumped through a bottle of sterile cotton into one filled with a 1 : 1,000 mercuric chlorid solution, and from this into the inverted cylinder surrounded by boiling water. The needles used are made by filing the end of an 18 gage aspirating needle to an angle of 45 degrees. There is also a nick filed into the needle about one-sixteenth inch from the end. Very good results have been obtained with this outfit.

Artificial Pneumothorax and Pregnancy. — The woman whose case Slater reports has been pregnant twice since pneumothorax treatment was begun. The first pregnancy ended in abortion at three months. The second ended at full term in normal labor without any interruption of the pneumothorax treatment.

Artificial Pneumothorax in Tuberculous Pneumonia. — Gammons suggests that this method of treatment should be used more often in these acute tuberculous infections.

Use and Value of Lane Plate. A. H. Harrigan, New York City. —p. 161.

Method of Increasing Osteogenetic Power of Free Bone Transplant.—The object of the experiments described by Brooks was to test the value of a method of increasing the osteogenetic power of the autogenous bone transplant, in order that a defect in the shaft of a bone of an old subject could be bridged by a free bone transplant with a better prospect of ultimate successful regeneration of the defect. Beginning on the fourteenth day after the second operation, the animals used were given intraperitoneal injections of 3 c.c. of a 5 per cent. solution of sodium alizarin sulphonate twice each week until the end of the experiments. The animals were sacrificed at the end of the periods of 23 to 173 days after the second operation, and the bones of the extremities removed for study. The use of the vital stain made it possible to determine the site and amount of all new bone formed from the transplants.

These experiments show a relatively large proportion of instances in which the ordinary bone transplant with periosteum and endosteum failed to regenerate a bone defect when the transplantations were made in animals which were not young. The experiments also show that transplants of growing bone result in a much larger proportion of successes than the normal bone transplants. The success or failure of a bone transplant obviously must be determined by both internal and external factors. The latent power of the osteoblasts to multiply and produce bone is an internal factor and would seem to depend on the intrinsic latent power or regeneration of the bone from which the transplant is taken. The adequate supply of nutrition for growth of the bone-producing cells must come from the bed into which the transplant is placed and is an external factor.

Whether the failure of a relatively large proportion of free bone transplants in old animals is the result of internal or external factors is not clear. It would seem most probable, however, that it was the result of the low intrinsic osteogenetic power of the bones in advanced life. It is also not clear from these experiments whether the growing bone transplant is successful in a larger proportion of instances than the normal bone transplant, because it contains cells with greater power of growth or because the growing tissue with its numerous thin-walled vessels and tissue spaces more readily acquires nutrition from the bed in which the transplant is placed. It would seem more likely that the latter is true. If this is so, then the transplant would possibly succeed in even a larger proportion of instances if the bed into which the transplant is to be placed were also stimulated to grow by previous operative procedure. These experiments show that when there is nonunion of fractured fragments in spite of good approximation of the fragments, the failure of the fracture to unite must be the result of poor regenerative power in bone.

In these experiments, in which only dogs well advanced in life were used, and in which the bones showed power of regeneration less than that in young animals, the conditions were comparable to those existing in clinical cases of nonunion of fracture as a results of poor regenerative power in the bones. The method of using transplants of growing bone resulted in a much larger proportion of successful results than those following the use of normal bone transplants. These experiments also showed that a defect in the bone of an old animal can be successfully repaired by bridging the defect with a homogenous transplant of bone taken from a young animal. In these experiments the growing bone transplants have been transplanted seven to twety-nine days after stimulating growth.

Advantages of Picric Acid Over Tincture of Iodin.—Gibson uses a 5 per cent. alcoholic solution of picric acid as a substitute for tincture of iodin. He has not seen any cases of irritation of the skin. The method has for some time been the routine mode of disinfection of the skin in the British armies.

Frequency of Adenomyoma of Uterus.—Between 1906 and 1918 (October 1) 3,388 fibromyomatous uteri were removed in the Mayo clinic. Two hundsed and eleven (6.43 per cent.) of these contained adenomyomas. In 5 cases the tumor was in the fallopian tubes. The last 109 cases of the series were studied by MacCarty and Blackman with reference to certain clinical features which might be associated intimately with the condition. Ninety-five patients (86 per cent.) were married; 41 per cent. gave histories of having had miscarriages; 50 per cent. suffered from profuse and prolonged uterine bleeding, and 31 per cent. from irregular bleeding. The average age of puberty was 14.3 years. Sixty-five per cent. of the married women had borne living children. In 5.5 per cent. of the cases epithelioma of the cervix or carcinoma of the body of the uterus was associated, neither of which conditions bore any apparent relationship to the adenomyomas. In 72 per cent. other pathologic pelvic conditions were associated, such as ovarian cysts, chronic or acute salpingitis, uterine or cervical polypi, cystic cervicitis or prolapsus uteri. In no case without the association of a malignant condition was the clinical diagnosis one of malignancy. In no case was a positive clinical diagnosis of adenomyoma made previous to operation. The clinical diagnosis was clothed in such terms as fibromyoma or pelvic tumor, both of which diagnoses show recognition of definite pathologic conditions of a neoplastic nature without attempting to specify in terms of detailed pathology.

Fracture of Upper End of Humerus.—Fractures of the upper end of the humerus, i. e., above the insertion of the pectoralis major muscle, according to Stevens, will in nearly all cases conform to three types and their subdivisions. Stevens insists that all should be treated in abduction and external rotation with traction varying from a few days in mild cases to twelve days in complicated ones. Passive motion must be begun early and active motion must follow very quickly if we are to prevent the tendency to restriction of motion. It must be used always with care and with due regard to the anatomy and pathology. In the mild cases it is safe to begin very early since there is little tendency toward displacement. A right-angled wooden splint in the severe cases and a firm pillow splint in the mild cases always with traction is the ideal method of treatment. External rotation in abduction as a treatment is almost an impossibility of accomplishment unless the patient remains in bed. In bed it is the simplest method and not an uncomfortable position for the patient.

Pneumonia and Empyema. H. Gray, Boston (to be continued).—p. 305.

Fracture Among Men Discharged from Army.—A total of 665 fractures were noted by Brewer among these 10,287 men, making a rate of 64.7 per thousand. In this group 15.2 per cent. of the fractures were of the humerus; 14.8 per cent. were Colles' fractures; 10.9 per cent. were fractures of the phalanges; 8.8 per cent. were fractures of the clavicle; 8.2 per cent. were fractures of the tibia; 7.7 per cent. were fractures of the femur, and 6.0 per cent. were Pott's fractures. Among the rarer fractures were fractures of the malar bone 1, two cases of fracture of the pelvis, and one case of fracture of a vertebra.

Aerobic Spore-Bearing Bacteria in Children.—A bacterial investigation of the dejecta of 74 children was made by Batchelor with the special object of isolating the aerobic spore-bearers. The findings were as follows: *B. cereus,* 32 cases; *B. albolactus,* 17 cases; *B. pseudotetanus,* 9 cases; *B. mesentericus,* and *B. subtilis,* each 6 cases; *B. petasites* and *B. vulgatus,* each 2 cases.

Bacteria from Polluted Water.—Nonlactose fermenting, nonliquefying bacteria were obtained by Kligler from 15 polluted wells and 14 contaminated subsoil samples. In but one instance were members of this group obtained from both the well and soil of the same premises, but even in this case the organisms possessed different biologic and serologic characters. The former belonged to the gas producing paraenteritidis group most common in the intestinal tract of swine, cattle, and other domestic animals. The latter, on the other hand, was a nongas-producing form resembling the bacillus found by Morgan, Lewis and others in the stools of normal individuals, as well as in those of people suffering from diarrhea. Kligler believes that a careful study of the nonlactose fermenting bacilli commonly found in the intestinal tracts of man and domestic animals might furnish the basis for an index of the source of pollution.

Study of Cellular Anaphylaxis.—In studying spontaneous phagocytosis in the liver with India ink the authors found that the ink particles were deposited only in restricted areas of the organ. It was evident that only a small part of the liver was traversed by the perfusing fluid. This observation suggested the possibility of making use of this procedure in studying the course of the perfusing fluid through an organ and in determining to what extent it is possible to wash an organ free of blood. All perfusions, whether of liver, lung, or uterus, give about the same results. It was never possible to wash out all the blood and albumin. The fluid from the exit cannula soon becomes free of albumin and blood, but if the perfusion is discontinued for a few minutes both these substances reappear. By perfusing organs with Locke's solution containing India ink, thus marking the course taken by the fluid through the organ, it was found that a surprisingly small part of the capillary system is really washed out by the perfusing fluid. This technic does not, therefore, remove circulating antibodies completely, as has been assumed, and this type of experiment does not establish the presence of cellular antibodies.

Disinfection of Drinking Water.—Fantus' work was done for the purpose of comparing the disinfectant value of halazone with that of chlorinated lime. He claims that chlorinated lime is a more efficient water disinfectant than halazone, compared on the basis of active chlorin. It is also a great deal cheaper. Hence, there is no reason for employing halazone in water disinfection, except when its superior tablet-making qualities render its use advantageous. Halazone is a better agent for the preparation of water disinfecting tablets. Its action is, however, a rather slow one.

Antigens in Wassermann Reaction.—In the tests reported by Ruediger, made on the serum of fifty supposedly nonsyphilitic persons and thirteen known syphilitics, six different antigens were used. With the serums from fifty clinically nonsyphilitic persons, alcoholic extract of human heart, alcoholic extract of beef heart and alcoholic extract of rabbit heart gave negative results. Alcoholic extract of dog heart gave positive results with sixteen, or 32 per cent., and alcoholic extract of guinea-pig heart gave positive results with seventeen, or 34 per cent. As no other signs or symptoms of syphilis could be discovered, these were considered false positive results, and, therefore, heart of dog and of guinea-pig are considered unsuitable for the preparation of so-called antigen to be used in the Wassermann reaction. Whenever alcoholic extract of dog heart gave a positive result, the alcoholic extract of guinea-pig heart also gave a positive result; the latter usually reacted somewhat stronger then did the former. With serum from known syphilitics, the alcoholic extract of beef heart and the alcoholic extract of rabbit heart frequently gave stronger positive results than did the alcoholic extract of human heart. The results obtained with alcoholic extracts of dog heart and guinea-pig heart corresponded to those obtained with alcoholic extract of human heart, while the alcoholic extract of sheep heart reacted weaker. When antigen was added fifteen minutes after the complement the same results were obtained as when antigen was added fifteen minutes before the complement. Antigen dilutions of 1:35, 1:45, 1:50 and 1:75 gave results that were identical with those given by a dilution of 1:25. Dilutions of 1:100, 1:200 and 1:300 gave irregular results, sometimes stronger, sometimes identical with and other times weaker than those given by a dilution of 1:25. Dilutions higher than 1:300 usually gave weaker positive results than did the dilution of 1:25.

Prevention of Droplet Infection by Face Mask.—Since June 1, 1916, gauze masks have been used by the nurses of the Durand Hospital. No case of scarlet fever has occurred since masks have been worn. The nurses are instructed to change the mask as soon as it has been known to be grossly contaminated, and never to put the hands to the mask to adjust it, etc., until the hands have been washed thoroughly. Early in 1918, bacteriologic tests showed that the masks then in use did not remove all the bacteria thrown out in the mouth spray. The masks consisted of two layers of gauze, 28 by 24 mesh, but as they were worn but once before washing and resterilizing, shrinkage soon made the openings in the gauze much closer than they were in the new masks.

Experiments made by Weaver demonstrated that gauze will remove bacteria from the air when carried in a moist spray. The efficiency of the gauze as a filter is in direct ratio to the fineness of the mesh and the number of layers used. Furthermore, it was noted that when the subject coughed with mouth wide open few bacteria were driven out, but that an explosive cough with the lips held quite close yielded quite a rich bacterial spray. The coarser gauze allowed a large proportion of the bacteria to pass through, even when six layers were superimposed. The finer gauzes removed many more of the bacteria, and when six and eight layers were used almost all the bacteria failed to pass through. The test was rather severe, as the force used was greater than that made in any spontaneous expiratory effort. Similar results were obtained when the pharynx and tongue had been smeared with a culture of *B. prodigiosus* shortly before the experiments were carried out. There appeared no appreciable difference between dry and moist gauze filtering properties. Since the completion of these studies the masks used in the Durand Hospital have been made of three layers of gauze with a mesh of 44 by 40. The nurses are instructed to wear two superimposed masks, making six layers of gauze, when caring for cases of virulent infections, when secretions are abundant. The gauze used is absorbent.

The experience with masks has been confined principally to their use to protect attendants on the sick from infection. They have been used not only by nurses, but by physicians in their work while taking cultures from throats, doing intubations and examining chests. Masks have also been placed over the faces of mothers while nursing their babies when either one has been infected by diphtheria or has been a diphtheria carrier. There has been considerable reduction in cases of rhinitis, tonsillitis, and pharyngitis among the nurses since masks have been worn. Weaver cautions that endeavors to limit droplet infections should not prevent equally energetic efforts to close other channels of spread of infectious materials.

Milk Sickness and White Snake Root.—Sackett's investigations show that trembles or milk sickness may be due to the ingestion of the toxic substance present in Eupatorium leaves.

Fats in Immune Processes.—The work discussed by Warden in this paper is a continuation of earlier work (abstracted in The Journal, Jan. 4, 1919, p. 71) in which it was shown that the fats peculiar to certain bacteria and other cells constitute their specific antigens, as shown by complement fixation antibody production in animals inoculated with the antigens, and by a new specific precipitation reaction in vitro between the fat antigens and their appropriate serum antibodies. This paper deals with the quantity of antibody produced in rabbits from inoculations with the pneumococcus and the streptococcus fat antigens and the amount of protection afforded against the organisms.

The facts brought out in this work on the functions of antigenic fats in immunity lead Warden to believe that such antigens are destined to play an important part not only in active immunization of animals and man as prophylactic measure, but also in the treatment of infections. They have to commend them their purity, the dosage by weight, the absence of toxicity, the ease and safety of either subcutaneous or intravenous injection. This form of treatment would appear to be particularly applicable to the types of infections of acute and often fatal character and of brief duration when antibody production is invariably slight or absent altogether, and where toxemia is the dominant symptom, such types being represented by pneumococcus, streptococcus and meningococcus infections. In infections also of a more prolonged course, such as typhoid and paratyphoid fevers, even when antibody is known to be present in the serum, as shown by agglutination tests, at the same time with the antigenic micro-organism, the fat antigen would be presumed to be beneficial both by increasing the antibody production and by furnishing a nidus round which the antigen-antibody aggregate might form and lead to the absorption of complement.

Atypical Clinical Types of Tuberculosis.—While admitting that tubercle bacilli may lodge in the human body and produce lesions without causing abnormal sensations which will attract the attention of the host, Head firmly believes, however, from a considerable experience, that these cases are rare, and that if all persons infected could be kept under skilled observation, the disease would make itself manifest in the vast majority of persons in sensations sufficiently pronounced to call their attention to the fact. Head is confident that every person giving a symptom complex, to account for which no definite causal factor can be found, should be given a subcutaneous tuberculin test to determine whether or not a tuberculous lesion is harbored. The confusing clinical picture presented by these slow, low-grade tuberculous toxemias cannot be interpreted otherwise. In 163 such cases in whom, for one reason or another, a subcutaneous diagnostic dose of tuberculin was given, a distinctive temperature rise and other signs indicative of a positive reaction were noted.

By far the largest group of cases fall into what Head terms the "cough and cold" group. These comprise 34 per cent. The second group he classes as the "abdominal distress" group. Twenty per cent. of the whole number fall into this category. The chief characteristic of this group of cases is the ill-defined nature of the abdominal complaint not fitting in well with a diagnosis as applied to disease of any one of the organs to which one ordinarily looks for the production of abdominal symptoms, namely, the appendix, gallbladder, pancreas, stomach or duodenum. About 15 per cent. of the cases fall into what is called the "chest pain" group. Many of the ill-defined neck aches which so-called neurotic women complain of, Head believes, are undoubtedly referred pains from forms of tuberculous pleurisy localized in small patches in the upper part of the chest, oftentimes in the extreme apex. In about 18 per cent. of these cases the chief symptoms complained of by the patients were those of physical and nervous exhaustion. A small percentage, 5 per cent., fall into the "malnutrition" group. In another small group of cases, 5 per cent. of the patients complain of a persistent pain in the back, low down over the lumbar region, either on both sides or the right or left side.

Radium Treatment of Menorrhagia.—In Stacy's opinion radium is the treatment of choice in (1) cases of hemorrhagia of menopause not associated with large fibroid tumors, and in which the possibility of carcinoma is definitely eliminated; (2) cases of menorrhagia in patients between the ages of 35 and 40 years, who have small submucous fibroid tumors, or, who have undemonstrable lesions; (3) cases of myomas in which there is a definite contraindication to operation; (4) cases of menorrhagia in the young person, who has resisted all medical treatment, in which very small doses should be given. In the majority of patients of more than 45 years of age; and in all in which there is intermenstrual bleeding, a diagnostic curettement is done by the Mayos previous to the radium treatment. If the clinical history is at all suggestive of a carcinoma of the fundus, a hysterectomy is done, for even a very thorough curettement may fail to reveal a carcinomatous focus. The dosage of radium is gaged by the age of the patient, and by the presence or absence of a tumor.

In the young person without a demonstrable tumor, and when it is desirable to continue menstruation, usually one application of 50 mg. of radium element for from four to six hours (200 to 300 mg. hours radium) is used. In older persons in whom it is desirable entirely to stop menstruation, it has been found that an exposure of 50 mg. for from ten to twelve hours has brought about the desired results. In cases in which large dosage is used, menstruation is usually irregular for about two months and ceases entirely after the second or third month; following the lighter exposures it becomes regular and normal in most instances in about two months.

It is the custom not to repeat the treatment until an interval of three months has elapsed. If, after that time, menorrhagia continues, a second treatment is given. It has been necessary to give a second treatment in ten instances in this series. In eight instances a hysterectomy was done later; one elsewhere one month after the radium treatment. One only of these eight patients had been given a second radium treatment. Reports have been received from 143 of the 175 patients treated and in fifty-five (38.5 per cent.) menstruation had ceased, not to return to the date of the report; in only fourteen did the menstruation become normal; in forty-two it was reported as regular but somewhat profuse, and in thirty (20.9 per cent.) it became profuse. Ninety-two patients report their condition as improved, and twenty-seven as not improved.

Hemoprotein Treatment of Arthritis.—The protein used by Brooks and Stanton for the purpose of combating streptococcus infections was prepared from ox blood fibrin by peptic and hydrochloric acid digestion, the products of this digestion being fractionated by precipitation with ammonium sulphate, the first fractions being rejected and the lower ones used. The protein is prepared in a dry state and kept in hermetically sealed glass ampules. These ampules are sterilized by heat. When used, the dry sterile powdered protein is dissolved in sterile 0.9 per cent. sodium chlorid solution and used at once by intravenous injection with aseptic technic. In some cases intramuscular injections were made. The matter of dosage does not seem to be very definite. Anywhere from 10 to 60 mg. seems to do equally well. The authors use ordinarily about 20 to 25 mg. intravenously and about 30 or 40 or more intramuscularly. Nine cases are cited.

Method for Determining Type of Meningococcus Infection.—The method used by Robinson is as follows: The spinal fluid from the patient is centifuged until clear; 0.5 c.c. of this fluid is added to an equal amount of each of the four type serums; the tubes are thoroughly shaken and warmed to 37 C. in a water bath. If a positive reaction is obtained a distinct flocculent precipitate forms in a few minutes.

"Propeller" Fracture.—Four cases of supracondylar fracture of the right humerus, caused by aeroplane propellers are reported by Johnson. The history of the injury is as follows: To start a nonself-starting aeroplane an air mechanic grasps a blade of the propeller and then turns it. At the same time the pilot opens the throttle in order to flood the cylinders with gas. At the word "contact" from the mechanic the pilot throws the switch into contact with the magneto, causing a spark, which ignites the gas and starts the engine. If the "team work" is faulty the mechanic is liable to be struck down by the propeller before he can escape. This was the history in the four cases forming the basis of this note.

New Germ of Paratyphoid.—In many specimens of blood examined by Hirschfeld for typhoid or paratyphoid, germs have been isolated by culture in bile which behaved bacteriologically like paratyphoid bacillus B, but were not in the least agglutinable by the corresponding specific serum, while the serum of the patient agglutinated the germ even in dilution 1:800. The clinical picture, temperature, etc., of patients infected by this germ is that of paratyphoid fever. From a bacteriologic point of view, there is no difference between the germ in question and the bacillus paratyphoid B. Hirschfeld looks on it as being a serologic variety of paratyphoid B, provoking, clinically, paratyphoid fever. This bacillus can be very virulent. Besides finding the bacillus in one patient who died of the disease, Hirschfeld isolated the same germ postmortem from the heart of a patient who succumbed to paratyphoid.

Tetanus in British Armies in France.—Of the 376 cases analyzed by Cummins and Gibson, 252 patients died and 124 recovered, a mortality of 67 per cent. Of the total deaths, 13 were from causes other than tetanus. The 376 cases fall into four groups: (*a*) Cases among British casualties, 291; (*b*) cases among men suffering from "trench feet," 24; (*c*) cases due to accidents and other causes, 48; (*d*) cases among German prisoners of war, 13. There were 278 cases of severe sepsis with 194 fatalities and 74 cases of gas gangrene with 56 fatalities. The time between wounding and the onset of tetanic symptoms varied from eighteen hours to 180 days. Of the fatal cases, the average period was twelve and a half days, and of the 112 recoveries fourteen and nine-tenths days. Tetanus occurred after amputation affecting the upper or lower limbs in 59 cases; 38 patients died as a result of tetanus and 15 recovered, while 6 died from sepsis and other causes after the tetanic symptoms had subsided. Among the 59 cases, 42, or 71.1 per cent., occurred after the amputation of the lower limb, and 16, or 27.1 per cent., after amputation of the upper limbs, while in one case both an upper and a lower limb had been amputated. Among the cases of amputation of the lower limbs in which tetanus subsequently developed the mortality was 76.3 per cent.; in the case of the upper limbs 60.0 per cent. Operative interference was resorted to after the appearance of tetanic symptoms in 27 cases. Of these, 22 died, a mortality of 81.48 per cent.

Nearly one fifth of the total number of cases occurred among persons to whom no inoculation had been given. Of the 376 cases, all but four, each of them fatal, were treated with antitoxin administered by the intrathecal, the intravenous, the subcutaneous, and the intramuscular method. The intramuscular combinations were attended with the smallest mortality and the intrathecal with the highest of the three, the intravenous route presenting dangers which are not encountered in the other three routes. In view of the great importance of making available at the earliest possible moment the largest possible dose of antitoxin, the authors consider that, in any given case, all three routes should be made use of, the intrathecal channel being exploited with the others as far as its limitations permit. As to the value of antitoxin treatment in tetanus, a steady fall in mortality has undoubtedly taken place, but it is urged that the greatest caution should be exercised in attempting to draw definite conclusions as to how this improvement has been brought about. When serum therapy is employed, the authors are strongly of the opinion that the antitoxin should be given at the earliest possible moment and that it should be given in large doses.

Intravenous Injection of Potassium Iodid.—In a typical case of tabes dorsalis seen by Devota, improvement followed after three intravenous injections of potassium iodid (30 grains dissolved in 4 ounces of normal saline solution); the shooting pains in the legs and feet disappeared entirely.

*Traumatic Obliteration of Artery. J. Babinski and J. Heitz.—p. 529.
Experimental Arrhythmia of Undescribed Type. H. Busquet.—p. 550.

Traumatic Obliteration of Arteries.—Babinski and Heitz emphasize the importance of extremely careful analysis of the symptoms because these traumatic lesions generally involve more than the artery; the nerves are frequently injured, and the secondary disturbance from fibrous myositis and gangrene confuse the clinical picture. Other symptoms not directly connected with the obliteration of the arteries may also intervene, changes in the temperature and color of the region, or there may be reflex disturbances, edema or retraction. They review their extensive war experience in this line, saying that sluggishness in electric reactions and in certain reflexes may accompany hypothermia and have the same significance, from the lesser supply of blood, the long immobilization, and possibly reflex vasoconstriction.

*The Rashes in Varicella. J. Comby.—p. 57.
*Tardy Relapse in Meningitis. A. Netter.—p. 72.
*Intraspinal Echinococcus Cyst. J. C. Mussio-Fournier.—p. 80.
*Present Status of Meningitis. J. Comby.—p. 90.

The Rashes in Chickenpox.—Comby applies the term rash to a premonitory eruption preceding the principal eruption in varicella, smallpox, measles, etc. It is probably an infectious or toxi-infectious erythema associated with the principal disease. It may suggest the possibility of a coincident scarlet fever, when such does not exist. In about 90 per cent. of the cases, this rash resembles the eruption of scarlet fever. In the others it suggests measles or rubeola until the chickenpox eruption becomes unmistakable. He describes nineteen cases, but adds that it occurs probably in not more than 1 or 2 per cent. of the cases of varicella. It usually precedes the principal eruption but exceptionally it may develop the third or fourth day of the eruption or at its close. In any event, it is ephemeral and is not accompanied by desquamation. Demme has reported a case in which the scarlatiniform rash recurred and preceded three waves of the varicella eruption. In one of Comby's cases a boy of 2 presented first a scarlatiniform rash and six days later a measles-like rash, at the beginning and in the course of his varicella. It does not require any treatment. One of his cases teaches that when smallpox is epidemic, it is better to vaccinate every one, young and old alike, regardless of their previous vaccination. In this case a child under 4 had a good vaccination mark but developed the scarlatiniform rash and a day later several papules which proved to be smallpox. Measles developed at about the same time, probably a hospital contagion. The child had been known to have been exposed to smallpox, but on account of its vaccination scar the disease had not been recognized. It was mild with prompt recovery.

Tardy Relapses in Cerebrospinal Meningitis.—Netter remarks that the polyvalent serums now used have rendered relapses in meningitis much less frequent, but in about 1.14 or 1.56 per cent. of his 350 meningitis patients there was a tardy relapse after thirty-three, forty-five, sixty or seventy-three days. In the two cases in which serotherapy could be applied promptly, the children recovered; the others were moribund when first seen. In order to ward off anaphylaxis, a small preliminary injection of serum was given before the serotherapy was started. In one case the relapse was unmistakably the result of an intercurrent measles in the infant of 8 months. In a boy of 11 the relapse followed two months after intercurrent measles plus diphtheria, and proved fatal. In one of the cases a girl of 5 seemed to have entirely recovered after the attack of meningitis, but other members of the family presented cases and the little girl developed the disease anew, after four months, probably from new infection as she had seemed perfectly healthy in the interim, while there was every opportunity for new infection in the environment. One young soldier developed extreme agitation, cyanosis, the feet and hands cold, with acceleration of the respiration and thready pulse, one hour after the intraspinal injection of the antiserum, nothwithstanding that the antiserum had been given subcutaneously twice just before, the first time 1 c.c. of a 10 per cent. solution of the antiserum, followed an hour later by 1 c.c. of the pure antiserum. The anaphylactic reaction was manifest for about three hours before complete disappearance. Two subcutaneous injections of ether seemed to have aided in its subsidence. A similar reaction followed the second intraspinal injection but it was less pronounced and briefer. The Besredka desensitization had evidently not warded off all phenomena of anaphylaxis but it seemed to have rendered them less severe than they might otherwise have been. This patient had been injected with a total of 260 c.c. of the antiserum in January and the relapse occurred in April. The first attack had left some contracture of the right side, and epileptiform symptoms developed after the second attack, suggesting that the latter was the flaring up of a latent focus. Although apparently recovered by June, he still has occasional epileptiform attacks.

Intraspinal Echinococcus Cyst.—Fournier's report was summarized in THE JOURNAL, Dec. 14, 1918, p. 2031, when it appeared elsewhere.

Meningitis.—Comby analyzes Simon Flexner's recent publications on prevention and specific treatment of epidemic meningitis.

Sequels of Gassing in War.—Achard reports on 3,525 cases of persisting injury from war gases. The mustard gas type was responsible for 84 per cent. of these cases of sequelae, but the injuries from gases of the asphyxiating type were the most serious. The degree and extent of the injury of the lung can be estimated approximately by the reduction in the amount of carbon dioxid exhaled per pound and per hour. There may be a tendency to emphysema or to a pseudotuberculosis. The importance of not mistaking these sequels of gassing for true tuberculosis is evident; the man's whole future may be blasted by a mistake of this kind. The lungs cast no shadow, the sputum does not contain albumin or only for transient periods; the fever and the physical signs grow less and less, and after several months or a year the man is found free from symptoms. In one such case the fever kept up for thirteen months but then permanently subsided. In another case there were signs of bronchitis and suspicious apical lesions with hemoptysis, weakness, loss of flesh, and fever compelling repose. As late as two years after he had been gassed, the evening temperature often rose to 38.5 C. Not until after two years and four months was the temperature definitely apyretic, and the general condition began to improve. The gas in these two cases was of the chlorin type. The danger of superposed tuberculosis has not proved as great as anticipated, but cases have been encountered now and then. Only six passed through Achard's service, and the gassing may have merely aroused a latent disease. Experiments on laboratory animals seem to confirm that the toxic action of the gas in the lungs does not create an especially favorable soil for the development of tubercle bacilli.

Experience has shown that the sequels on the part of the eyes have not been as numerous or as severe as had been feared; keratitis is rare, but cicatricial deformity of the eyelids and of hands and joints and genital organs is more common, and may require operative correction. Among the other sequels, septicemic infection, fortunately very rare, is a formidable secondary complication of the blistering burns from gas. Anemia and asthenia are frequent, and long persist. Treatment of the sequels of gassing requires nothing special except that respiratory gymnastics will be found useful in helping to overcome the sequelae affecting the lungs. Exercises with the spirometer and the spiroscope and exercise of the chest muscles can be recommended. In the discussion that followed, a leading ophthalmologist stated that he had encountered only three cases of total blindness from gassing. Unilateral lesions were more common, mostly ulcerative keratitis infected with the pneumococcus.

Training of the Left Hand.—Armaingaud appeals to the authorities to take advantage of the opportunity that so many wounded men are being trained to use the left hand to introduce systematic training of both hands into the education of the young. He declares that we have no right to impose on the young this artificial disability by omitting to train both hands. Among the arguments cited is Benjamin Franklin's witty appeal in which "Left Hand" protests against the partiality shown her sister, "Right Hand." Armaingaud urges parents to train both hands from early childhood, and that the school authorities should insist on both hands being used in writing and other exercises. He suggests that some endowed prizes for teachers might promote the cause of training the left hand.

Arsphenamin in Influenza.—Bruhl and Franck gave arsphenamin by the mouth and by the vein in thirty-eight cases of the gravest forms of influenza when the epidemic was at its most murderous height, as they say. The death rate in this group was 21 per cent., which they regard as a striking result under the circumstances.

Bacteriology of Influenza.—Dufour reasoned that the prevalence of pulmonary lesions in influenza testifies to the affinity of the germs for oxygen. Consequently he arranged the culture medium so that oxygen bubbled into it at times during the first two days. A diplococcus taking the gram was cultivated from the blood in large numbers by this means, while the nonoxygenated mediums showed no cultures.

Anemia with Infectious Jaundice.—The jaundice in Ribadeau-Dumas' case had been observed at intervals for a year, with periods of fever, and the anemia and weakness finally became extreme. The reds numbered only 530,000 when 250 c.c. of citrated blood were infused. It was followed by a chill, but in five hours the reds numbered 1,300,000. Six days later another transfusion apparently completed the cure; in a few weeks the man's aspect and liver outline were those of health.

Exophthalmic Goiter and the Bombardments.—Etienne and Richard relate that the repeated violent bombardments of Nancy from the big guns and aeroplanes enabled them to study the effect on the endocrine glands of emotional stress. In two women of 24 and 34, exophthalmic goiter developed in an acute form with high blood pressure. In two other young women the blood pressure was below normal. They note further that in some women menstruation was arrested by a bombardment; glycosuria was brought on in other cases. In one man of 36 symptoms of Addison's disease appeared and these were followed by the symptoms of exophthalmic goiter. These latter symptoms subsided in three months but the Addison symptoms persisted to a fatal termination in about eighteen months from the first signs of trouble. The nervous crises appeared first after the destruction and bombardment of La Courneuve at Paris, close to his home. In four days the skin showed bronzing, with patches on mucous membrane, rapid pulse and low blood pressure. This case corroborates the possibility of an emotional origin of Addison's disease as has been demonstrated for cases of exophthalmic goiter under similar stress. In two other cases Addison's disease became superposed on preexisting exophthalmic goiter. Exophthalmic goiter of emotional origin may thus develop under the influence of suprarenal hyperfunctioning, but it can also develop with suprarenal hypofunctioning, and suprarenal trouble may also become superposed on exophthalmic goiter. In two cases of this latter type, the bronzing is extreme, but one man is still at work ten years later, and all the symptoms have subsided in the other.

Acute Nephritis.—The healthy young sailor developed acute nephritis, with 61 gm. albumin in the urine, a few days after being in the water for several hours when his ship was torpedoed. Apparently complete recovery followed in less than three months.

Walled Off Meningitis.—Marcland injected antimeningococcus serum directly into the ventricles of an infant only 4 months old who presented symptoms of a meningitis that had become partitioned off. The meningitis had apparently subsided when the skull began to enlarge, with return of severe symptoms of meningitis, about five weeks after the temperature had returned to normal. About 20 c.c. of the antiserum was injected into one ventricle and 10 c.c. into the spinal cavity, after 70 c.c. of fluid under high pressure had spurted when the ventricle was punctured. The other ventricle was injected three weeks later with 40 c.c. of antiserum, with 10 c.c. in the spinal cavity, and then all symptoms retrogressed. Now, three months later, the child looks well nourished and otherwise normal except for blanching of the disks, but vision has been fairly recuperated in one eye and there is perception of light by the other eye. Notwithstanding that only four injections of antiserum were made in the course of nearly ten weeks, the meningitis and the secondary pyohydrocephalus completely retrogressed. He has compiled 7 cases of walled off meningitis discovered only at necropsy; 18 in adults with 40 per cent. of recoveries after intraventricular injection of the antiserum, and 11 in infants, with recovery in nearly 50 per cent. In the 6 fatal cases a focus was found at some other point in the brain, explaining the lack of success from the intraventricular injection. In the case here reported, the small amount of fluid obtained early in the meningitis by lumbar puncture should have warned that the communication between the brain and spinal cavity was already more or less obstructed, as even then there were signs of hypertension in the brain. The facility of intraventricular puncture in infants should turn the scale in favor of applying it early, at the slightest suspicion of obstruction of communication. Prompt puncture may ward off hydrocephalus and blindness. When slight or no benefit is observed, a third focus, bulbocerebellar, may be assumed. It is isolated from the local treatment above mentioned but might be reached by the orbitosphenoidal route described by Bériel of Lyons.

Falling of the Hair After Influenza.—Thibierge has been impressed by the number of the men and women who complain that their hair is falling out since they had influenza. The alopecia seems more rapid and more intense than usually follows infectious diseases, but the hair soon begins to grow again except with those with an inherited tendency to baldness. Stimulating local applications and general tonic measures aid in the recuperation.

Journal de Médecine de Bordeaux

Feb. 15, 1919, **90**, No. 3

*Grafts of Adipose Tissue. W. Dubreuilh.—p. 47.
*Suture of the Lung for War Wounds. Brau-Tapie.—p. 50.
*Fixation Abscess in Treatment of Influenza. J. Vergely.—p. 57.
*Transient Epidemic Amaurosis. Verger and Moulinier.—p. 61. (Society Proceedings.)

Grafts of Fat Tissue.—Dubreuilh has been very successful in remedying deformity from cicatricial retraction of the muscles of the face by introducing a flap of adipose tissue to fill up depressions. He operates under local anesthesia, excising the superficial cicatricial tissue with the epidermis; what is left becomes spontaneously resorbed. The skin around is loosened up for quite a distance so that it can be drawn up to cover the gap. When all is ready for the flap he cuts it from the adipose tissue in the front or side of the thigh. He sutures with very fine catgut; the two ends, each in a much curved needle, are worked in and crossed like the lacing of a shoe, the stitches only 0.5 or 1 cm. apart, the threads crossing each time. The suture is entirely intradermal, and the ends are tied together, cut off close and buried. If the stretch to be sutured is long, he ties the catgut ends and begins anew at different points, thus suturing in relays. As it is difficult to suture over the slippery fat tissue, the suture is made first but left loose. It is an easy matter then to slip the flap of fat under the suture and then draw the threads tight over it. Even if suppuration occurs and the graft is cast off, it is not expelled like a sequester but seems to melt away, and the cosmetic result may be good even with this.

Suture of the Lung.—Brau-Tapie has had recently in his charge sixty-three cases of war wounds of the chest. In eleven operative intervention seemed indicated, and six of these men were evidently saved by it. Resection of the third or fourth rib in the anterior wall for a distance of 5 cm. gives ample access to the lung; from the rear it is almost impossible to draw up any part of the free lung. Even when the wound is in the rear of the lung, it can be reached more readily from the anterior wall. After evacuating all the fluid blood and the clots in the pleural cavity, he rinsed it out with ether, and the pulse and respiration did not seem to be modified by this. His experience teaches that surgical intervention is called for when the pulmonary hemorrhage continues and the projectile is as large as a nut or larger. Intervention should be complete when possible. The hemothorax consecutive to the intervention should be punctured four or five days later.

Fixation Abscess in Treatment of Influenza Pneumonia.—In Vergely's 143 cases of influenza he never encountered the form with acute pulmonary edema which others have described, but in other bronchopulmonary complications he found the fixation abscess an important adjuvant to the ordinary measures in fourteen cases.

Epidemic Amaurosis.—Verger and Moulinier reported at a January meeting of the Société de Médecine et de Chirurgie of Bordeaux the occurrence of a small epidemic of transient blindness. Three of the five persons on board a small vessel soon after its arrival were taken suddenly sick, and complained of loss of vision but there was no fever; two died within three days, a man and a woman. The man who recovered became blind the fourth day. After twelve days of amaurosis, vision gradually returned, although there were still evidences of optic neuritis. Three other cases of the apyretic amaurosis developed in the same locality, without contact with the first group. One of the men was just recovering from influenza. He told that a veil seemed to be drawn over his eyes, progressing from left to right, shutting off vision completely by the thirty-sixth hour. The veil gradually passed off in the same way, from left to right. No causes of possible common intoxication could be discovered, but in the second group influenza might possibly be incriminated.

*Sciatica. J. A. Barré.—p. 57.
*Autovaccines in Treatment of War Wounds. L. Julien and De Lareinty Tholozan.—p. 60.

Sciatica.—Barré's four illustrations show certain objective findings in the leg with sciatica. The discovery of any of them confirms the reality of the complaints of sciatic pain. These signs include a reduction in the temperature of certain zones in the leg affected, especially the lower half of the outer aspect of the leg. The patient must get out of bed for these tests, and walk around a little with bare legs and feet. The lower temperature can then be readily determined by applying the back of the index and middle finger to the skin. The observer's hands must be warm at the time. This hypothermia is often a very early and constant sign of sciatica, and may be the sole objective manifestation of it. The pain probably induces some superficial vasoconstricting reflex in the skin. Other signs reveal hypotonicity in the muscles. As the man kneels on a chair, the normal foot is in slight extension, while the foot on the side with the sciatica is held at an exact right angle; the region just above the heel also looks sunken in. A retromalleolar reflex can also be elicited on the side of the sciatica as the man kneels on a chair. This reflex precedes the Achilles reflex and atrophy of the Achilles reflex precedes the atrophy of the muscles of the leg. In treatment Barré warns against the use of the actual cautery. It does no good and may aid in simulation. When a man with sciatica says he cannot walk without a cane, Barré keeps him in bed until he thinks he can dispense with the cane. In mild cases of sciatica, massage, hot air douches, prolonged baths and rubs with chloroform liniment at first and then turpentine, with relative repose and some sedative, generally answer the purpose. He has had over a thousand cases of sciatica in the last few months. Epidural injections of sedatives and other substances never gave durable benefit. In extremely painful, acute cases, bed rest without moving or rubbing was the rule for the first few days, then wet cupping and mustard pastes along the most painful zones, with sedatives, gave rather prompt results. With this acute pain, ionization with solutions having an aconite base has given very encouraging results. He gives no details of this technic but adds that this simple method deserves wider adoption in the clinic.

Vaccine Therapy of War Wounds.—Julien and Tholozan have found a sensitized autovaccine extremely useful. They sow on gelose a loopful taken from the depths of the wound. After incubating for forty-eight hours, all the colonies that have developed are scraped off and are suspended in 5 c.c. of polyvalent serum. This sensitizes the germs present, and the vaccine thus prepared has the rapid immunizing properties of a prepared serum with the durable immunization conferred by a vaccine. The microbian emulsion is incubated at 37 C. for an hour and a half at least, then centrifuged, the sediment rinsed twice with physiologic serum, then heated twice, for an hour each time, to 50 or 60 C. The germs are then counted and diluted with physiologic serum until there are 50 million per cubic centimeter. Then 1 c.c. of this dilution is injected in the scapula region. Suppurations that had been keeping up interminably were promptly arrested by this vaccine therapy, which they think deserves wide application.

False Actinomycosis.—Gougerot warns that a number of other pathologic conditions may simulate the clinical and bacteriologic aspect of actinomycosis: syphilis, cancer and tuberculosis, besides various microbian skin affections and others. In one case described the cheek was supposed to be the seat of an extensive process of actinomycosis, but it proved to be a syphilitic osteomyelitic process, with sequesters and fistulas. In another case the foot was involved; ordinary treatment as for any pyodermatitis cured the lesion in thirteen days after it had been dragging along for three months under treatment for supposed actinomycosis. In two cases cancer simulated the latter, even to the "bacteriologic" findings until the microscope revealed the cancer in an excised scrap. The cancer fistulas discharged granules simulating the granules of the fungus, and filaments took the stain. Biopsy may be the only means to differentiate the case. Tuberculosis is most frequently confused with actinomycosis; even Poncet made this mistake twice. Gougerot has seen it made with tuberculous lesions in the parotid region, in the ilium, and on the chest. Inoculation of guinea-pigs here solved the problem. In one case a fistulous affection of the throat was cured by excision of the focus after failure of all measures addressed to actinomycosis.

Dislocation of the Foot Below the Astragalus.—Quénu discusses luxation inward and forward as well as backward and outward luxation.

Exploratory Arthrotomy of the Knee.—Descomps and Moulonguet describe the technic for extensive arthrotomy in the exceptional cases in which intervention of the kind is required.

*Deafness from Chenopodium Poisoning. E. Oppikofer.—p. 161.
*Acute Appendicitis in the Elderly. J. Dubs.—p. 172.

Chenopodium Poisoning and the Hearing.—Oppikofer adds another to the four cases he has found on record in which bilateral deafness developed in consequence of poisoning from chenopodium. The two adults and three children affected all presented symptoms showing severe general poisoning, to which the adult who had taken the largest dose succumbed. The others recovered in a few days to two weeks. He reviews the literature on chenopodium poisoning, saying that in none of the other ten cases on record was the hearing mentioned, so presumably the drug did not induce deafness. Staggering, extreme vertigo and inability to stand without support were recorded in the cases with deafness, suggesting impairment of the vestibular as well as of the cochlear functioning. The optic nerve seems to be more resistant to the origin, the patient recovered under medical measures alone. In the pneumonic and pleuritic cases operative measures are indispensable. He adds that resection of a rib is extremely simple, and marvelous in its effect. Only when there are several foci and they are small, medical treatment might have to be the sole resource.

Experimental Trypanosomiasis. M. Torres and J. Villaça.—p. 401.
*Blood Pressure in Malaria. C. Fraga and E. Boaventura.—p. 402.
*Glycerin in Conservation of Serums. A. Moses.—p. 403.

Blood Pressure in Acute Malaria.—Fraga and Boaventura have been making a special study of the arterial tension in different stages of malaria, finding that the blood pressure is subnormal, both the maximal and the minimal tension. This suggests the necessity for suprarenal treatment to supplement quinin in treatment of acute malaria, as the hypotension is a sign of sympathetic-suprarenal insufficiency. Fraga called attention last year to the characteristic difference in the tension and in the pulse when they were taken reclining and again when the patient stood up for the tests. He emphasized the importance of this orthostatic tachycardia as a sign of suprarenal insufficiency.

Conservation of Immune Serums with Glycerin.—Moses relates that the addition of chemically pure and neutral glycerin to hemolytic serums, complement fixators, agglutinating and precipitating serums serves to protect them against contamination and renders them durable. He advises using 50 per cent. glycerin. With this the serums can be kept in glass without fusing. He has found that the glycerin aided in the conservation of serum from patients, so that the Wassermann reaction or fixation of complement test could be applied with full precision months or even a year later.

*Scientific Pan-Americanism. C. E. Paz Soldan.—p. 3.
*Necessity for Unification of Scientific Efforts. E. Escomel.—p. 4.
*Influenza in Lima. C. E. Paz Soldan.—p. 5.

Scientific Pan-Americanism.—See news columns, March 22, 1919, p. 879.

The Instituto Oswaldo Cruz in Brazil.—Escomel was much impressed by the advantages of the organization of scientific efforts as he witnessed the working of the Instituto Oswaldo Cruz at Rio de Janeiro with its numerous branches scattered over the country. They are independent institutions to a certain extent, like the Butantan Snake Institute, but form part of a great whole which has the benefits of organization and a directing plan, an esprit de corps, emulation and devotion in scientific research and the production of therapeutic serums, vaccines, etc. He pleads for the establishment of a central institution of the kind in Peru.

Influenza in Peru.—Soldan relates that influenza appeared at Lima in a mild form in October, but the epidemic changed to be more serious toward the close of November, and by the end of the year the mortality totaled 600 deaths above the average. He notes that the deaths from influenza also contributed to raise the mortality from tuberculosis. The schools were closed during the first two weeks of November and the epidemic seemed to be under control when the celebration of the armistice or other reasons caused it to flare up with greater vigor. The Consejo Superior de Higiene took measures, December 17, to provide hospital facilities for the sick, and prohibited certain public gatherings but did not close the cinemas. The only measure that had been officially taken before this date was a decree dated November 28 for compulsory notification of cases of influenza, but this was not enforced.

Colored Glasses for Photophobia. V. Ribon.—p. 186.
Infant Feeding. R. Diaz V.—p. 194.

Premature Separation of the Placenta.—Canales was summoned to a woman of 42 nearly at term with her fifteenth pregnancy. A sudden agonizing pain and flood of blood from the vagina could not be explained by placenta praevia or rupture, only by premature separation of the placenta, which proved to be the case. The fetus was dead; the anemia from the severe hemorrhages was effectually combated. He cites authorities to show the rarity of this mishap, one in 7,000, one in 1,000, one in 800, according to different writers. The mortality of the mothers is said to average 60 per cent., and of the fetus 100 per cent. All recommend rapid clearing out of the uterus. Cesarean section is usually out of the question on account of the losses of blood. None of the causes usually invoked existed in the case here reported except the large number of preceding pregnancies. When the fetus and vagina had been expelled he took the uterus in his hands and expelled further a great quantity of clots, following this with an injection of pituitary extract. Under this, retraction promptly occurred while the ice-cold woman was warmed and stimulants given.

*Influenza in Paraguay. M. A. Moreno.—p. 785.
Psychology of the Aviator. II. J. A. Lopez.—p. 786.

Conservative Treatment of Rupture of Uterus.—Chamorro applied in a case described the method advocated by Boero at the International Medical Congress in 1910. The rupture was transverse and fully 10 cm. long, in the anterior face of the lower segment of the uterus, and the woman, a novipara, exhibited the symptoms of shock. Chamorro succeeded in grasping with his fingers the upper lip of the rupture at the extreme right, while an assistant forced down the uterus by pressure from without. A firm grasp with forceps was taken as the fingers let go, and the same procedure was repeated with the upper lip at the extreme left. By this means the whole of the upper lip was drawn down, closing the gap as one lip lapped over the other, the peritoneal aspect of one in contact with the uterine surface of the other. Gauze was packed in tight to hold the parts in position. The handles of the forceps were wrapped in gauze and the vagina packed firm, and the patient placed in Fowler's position, with ice to the abdomen and permanent proctoclysis. Seventy-nine hours later the forceps were removed, the last ones first. The temperature kept normal till the fifth day when a slight rise was combated with a purgative. There had not been much loss of blood, not over 300 gm., and recovery was smooth. Reexamined several months later the overlapping tissue can be felt as a linear scar, about 1 cm. wide, where the one lip laps over the other, and there has been no further disturbance at any time. Chamorro adds that the success in the case confirms that obtained constantly in other cases.

Blocked Pleurisy.—Pignetto relates that in puncturing the pleural effusion in a man of 45, after about 200 gm. of fluid had been evacuated, the man exhibited symptoms of distress and coughing and no fluid could be aspirated. Another trocar was introduced at a point farther along, and here the fluid flowed freely, 350 gm. being thus aspirated. The pleurisy was of the serofibrinous type and the man was a hard drinker, but recovery after the evacuation followed the usual course.

Vaccine Therapy of Tuberculosis.—Castromán writes from Montevideo to emphasize the importance of the mutations of the tubercle bacillus, and the necessity for taking them into account in vaccine prophylaxis and therapy in tuberculosis. He accepts Ferran's theory that the Koch bacillus represents merely the third or gamma stage in the evolution of the bacillus from an atoxic alpha form which induces the predisposing phlegmasia. The vaccine from this nonacid resisting, alpha form is the true prophylactic, he reiterates.

Influenza in Paraguay.—Moreno's experience with the mild and grave forms of influenza when it swooped down on Paraguay repeats what was observed in other countries.

EPIDEMIC ENCEPHALITIS (NONA)

PETER BASSOE, M.D.
Associate Professor of Medicine (Nervous and Mental Diseases),
Rush Medical College; Attending Neurologist,
Presbyterian Hospital
CHICAGO

Following Sainton,[1] we may define this disease as "a toxic, infectious, epidemic syndrome, characterized clinically by the triad lethargy, ocular palsies, and a febrile state; and anatomically by a more or less diffuse encephalitis, most marked in the gray matter of the midbrain."

The term "lethargic encephalitis," proposed by Economo[2] in 1917, is descriptive of the most important clinical and anatomic features; but it is illogical, as the patient, not the encephalitis, is lethargic. As there is no other form of encephalitis known to occur epidemically, it would appear sufficiently distinctive to designate the disease as "epidemic encephalitis." The term "sleeping sickness" has already been appropriated for the endemic trypanosomiasis of Africa, and should, therefore, be avoided in connection with the present affection. "Nona," a meaningless word used for a similar disease in 1890, has the advantage of being short as well as noncommittal, and should perhaps be revived.

EPIDEMICS, PAST AND PRESENT

It is a striking fact that the only epidemic appearance of any similar disease in the past has been in connection with epidemics of influenza. Following the pandemic of 1889-1890, the mysterious nona appeared in northern Italy and then in Hungary, and spread westward to Germany, France and Italy. Somnolence was a prominent feature, and cranial nerve paralyses were observed which led Mauthner[3] in 1890 to express the opinion that the probable lesion of nona was an acute hemorrhagic poliencephalitis. The disease was mild, and there were not enough fatalities to permit of any extensive anatomic study. A concise review of the nona literature was contributed in 1892 by a Frenchman, Longuet.[4] Earlier accounts are necessarily more vague. Càmerarius, who described a grip epidemic in Tübingen in 1718, mentioned a sleeping sickness (*Schlafkrankheit*) in connection with it. In 1768, Lepecq de la Cloture described a "coma somnolentum" after the grip, and Ozanann, who, in 1835, wrote a history of epidemic diseases, mentioned epidemics of "catarrhal fever" with "soporosité" as having occurred in Germany in 1745, in Lyons in 1800, and in Milan in 1802. Nona apparently was not observed during the influenza epidemic which swept this country in 1890, as it is not mentioned by Archibald Church[5] in his exhaustive article on the nervous complications and sequelae of the grip.

The present epidemic, like that of nona in 1890, first appeared in eastern Europe, in Austria, where the name "lethargic encephalitis" was given to it in 1917. Thence it spread westward, reaching France and England early in 1918, and this country in the fall of the same year. The etiologic relationship of this disease to influenza rests on the above described coincidence of the epidemics. It is not common for the individual patient to have had a clinically distinct influenza. The encephalitis may itself be a cerebral form of influenza, or it may be caused by a separate virus which in order to become active must have been in contact at one time or other with that of influenza. In none of the eleven cases which form the basis of the present paper had there been any definite preceding influenza. However, I have been impressed by the fact that nearly all of the patients whom I have seen had been in a more or less run down or exhausted condition prior to the onset, which condition may have predisposed to a localization of the virus in the brain. In this connection it is significant that the part of the brain chiefly involved, namely, the brain stem and basal ganglions, is particularly liable to be affected by poisons, whether exogenous or endogenous. It is this part of the brain which is most affected by gas poisoning and which is the seat of the sporadic poliencephalitis, particularly frequent in connection with alcoholism and other toxic states.

PATHOLOGY

I have had opportunity to make preliminary examination of the brains in two cases in which complete necropsies were performed. The two brains were very similar, the gross changes consisting of edema, congestion and minute hemorrhages, most numerous in the brain stem, basal ganglions and centrum ovale. The histologic changes are also similar in the two cases and are mainly found in the basal ganglions and brain stem down to the upper part of the bulb. They consist principally of dense accumulations of mononuclear cells around the vessels and of small hemorrhages. There is little evidence of necrosis or of extensive tissue destruction, in which respect this disease differs from poliomyelitis. This distinction is in accord with the clinical fact that paralysis is a much more conspicuous symptom of poliomyelitis than of epidemic encephalitis. Little or no evidence of inflammation was found in the cortex or the meninges, but there has not yet been sufficient time for a systematic examination of the entire brains.

SYMPTOMATOLOGY

The onset was gradual, and the early symptoms were usually attributed to the preexisting exhausted or toxic state. I do not know of any case with such sudden onset of severe general infection together with paralysis or other pronounced cerebral symptoms as in poliomyelitis or meningitis. The first suggestive symptoms have usually been blurring of vision with more or less definite diplopia, together with progressive listlessness which, when pronounced, is called lethargy. The facies gradually becomes extremely characteristic with masklike, immobile features, half open eyes and a fixed, more or less puckered or distorted position of the mouth. There is not so much real sleep as is indicated by the sleepy expression of the patient. In fact, some of the patients actually suffer from insomnia, and the "lethargy" sometimes bears about the same relation to sleep as the compulsive laughter of the pseudobulbar paralysis patient does to a normal laugh; or as the calm and stoic facies of the actually irritable and peevish paralysis agitans patient does to true serenity. In other words, the lethargic appearance is only a sign of the involvement of the cerebral mechanism of expression, as part of a general affection of the whole tonus-regulating apparatus.

In severe cases the whole body becomes rigid and all movements slow and labored, the condition resembling both catatonia and advanced parkinsonian rigidity. There is a good imitation of the flexibilitas cerea of the cataleptic state, and any attempted movement is likely to result in a coarse tremor. Some patients have crises of coarse tremor or choreiform jerkings attended with profuse perspiration and weak, rapid pulse. In one case, otherwise not severe, coarse jerkings, almost choreiform in type, have become very troublesome, and it is an interesting observation that this disturbance has been temporarily controlled by scopolamin.

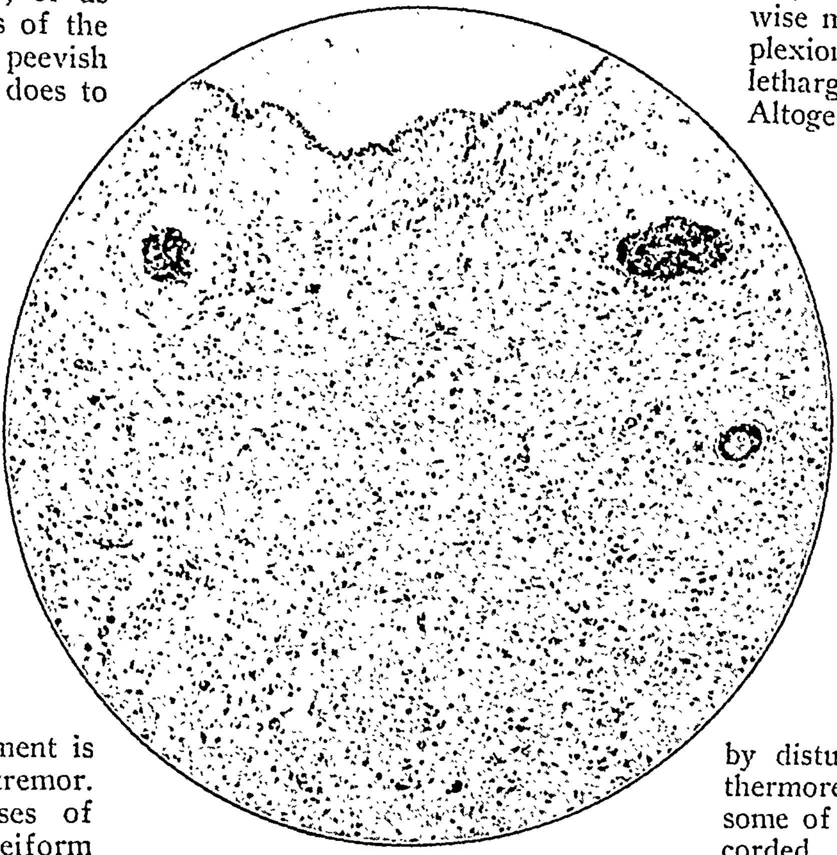

Fig. 1 (Case 2).—Left thalamus at floor of lateral ventricle: perivascular infiltration; × 80.

The frequently observed retention of urine and difficulty in speech and swallowing are probably in most cases part of the same type of disturbance which is due to affection of the above-mentioned tonus-controlling extrapyramidal motor apparatus. This apparatus, according to recent investigations, has its centers in the basal ganglions, which, as stated above, are among the favorite sites of the inflammatory changes in this disease. That the rigidity may exist without affection of the voluntary or pyramidal motor system is shown by the fact that the tendon reflexes, as well as the abdominal and plantar reflexes, may remain practically normal. True paralysis, even of the ocular and facial muscles, may be absent. It is possible to distinguish between the cases of principal involvement of the basal ganglions with the above-mentioned features, and cases with more pronounced pontine involvement, such as Case 1 in this paper. This patient had distinct external rectus and facial paralysis on the right side, and spastic paralysis with increased reflexes in the left arm and leg. In most cases we have a combination of the basal ganglions type and the pontine type, but it is always well to attempt to analyze the form of motor disturbance in the given case. The early tendency to ocular motor disturbance indicates primary involvement of the upper part of the brain stem around the aqueduct of Sylvius and the third ventricle. The fact that in cases of tumor and other circumscribed lesions in this region lethargy and somnolence are frequently mentioned has led previous observers to suspect the existence of a sleep center in this locality.

The early occurrence of the lethargy also points to its being a focal symptom rather than an expression of intoxication of the higher brain centers. In otherwise mild cases with good complexion and clear tongue, the lethargy may be very marked. Altogether it is safe to predict that careful study of the symptoms and lesions of this disease will help us to interpret many hitherto obscure symptoms, and throw a valuable side light on such affections as paralysis agitans, chorea, Wilson's disease and perhaps even dementia praecox.

Fever is usually present to a variable extent, but like the lethargy it need not always bear a direct relation to the amount of infection present and may even, to some extent, be caused by disturbance of the cerebral thermoregulatory apparatus. In some of the fatal cases here recorded, hyperpyrexia attended the ushering in of bulbar symptoms which caused death by respiratory paralysis. Anesthesias have not been seen, and headache and other pains have been inconspicuous. Consciousness is usually retained nearly to the end, though all forms of expression of it may be nearly abolished.

LABORATORY TESTS

The spinal fluid was always clear, sometimes under increased pressure, and usually showed a slight increase in globulin. The cell count was less than 10 in six cases, 10 in one, 25 in one and 26 in one. The cells were mononuclear. Results of cultures of blood and spinal fluid, both during life and after death, were negative. No bacteria were seen in sections of the brain. Leukopenia was observed in only one case; slight leukocytosis was observed more frequently.

REPORT OF CASES

Case 1.—*History.*—A girl, aged 9 years, referred by Dr. Bayard Holmes, Feb. 3, 1919, had been noticed by her mother to be cross eyed, Dec. 27, 1918, but this condition was not constant until January 12. On the following day, she was examined by an ophthalmologist, who found paralysis of the right external rectus. January 15, unsteadiness of gait was noticed, and on the 16th, she had difficulty in holding objects in the left hand. Within the next week, the left arm became paralyzed and, February 1, difficulty in swallowing set in. Indistinctness of speech was first noted about January 20. February 3, the patient was able to walk with aid into my office, but was weak and unsteady. She was admitted to the Presbyterian Hospital on the same day.

Examination.—The patient could walk with a little support, but dragged the left leg. The pupils, eyegrounds and visual fields were normal. Horizontal nystagmus was present. There was paralysis of the external rectus of the right eye. The facial muscles were weak on both sides, more on the right. The patient puckered the lips poorly and could not whistle. The tongue on protrusion deviated to the left. The neck was not rigid. The left arm was completely paralyzed, and there was loss of movement of the left toes and ankle. The tendon reflexes were markedly increased on the left side, and a left Babinski sign was present. Sensation was normal. The speech was slurred and almost unintelligible.

Lumbar puncture yielded a clear fluid with negative Wassermann test, while the Nonne-Apelt globulin test was weakly positive. The cell count was 4. The Lange colloidal gold test gave a rather strong reaction (2343321100).

The blood gave a weakly positive Wassermann reaction, as did the blood of the mother; but there were none of the ordinary symptoms of congenital syphilis.

Clinical Course.—During the following twelve days, the temperature every day ranged between 99 and 100, and the pulse rate was usually between 90 and 100. The leukocyte count was 7,100, February 4, and 9,250, February 8. For some days, the patient improved considerably in regard to talking and swallowing, but February 8 the speech again became very indistinct. The paralysis remained unchanged, and the ankle clonus and the Babinski sign were constantly obtained on the left side. The abdominal reflexes were absent. At noon, February 14, she suddenly developed respiratory difficulties and signs of pulmonary edema. At 7 p. m. she improved, but four hours later, the condition grew worse, and she died at 1 a. m., February 15. Necropsy was refused.

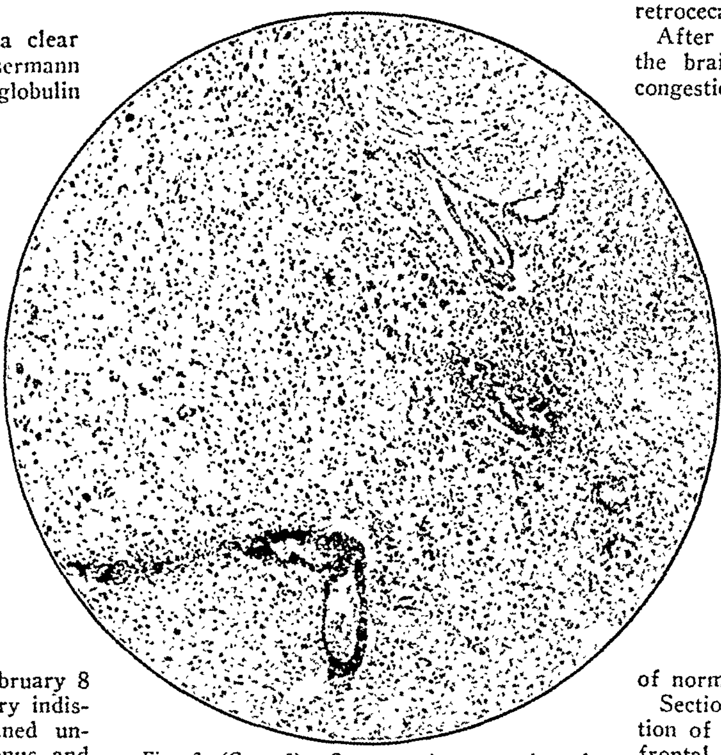

Fig. 2 (Case 2).—Corpus striatum: perivascular infiltration and diffuse inflammation; × 65.

Case 2.—*History.*—A married woman, aged 34, who had borne eight children and who was now in the sixth month of pregnancy, seen, Feb. 10, 1919, with Dr. Paul Kelly, about three weeks previously had become listless and complained of fatigue and headache. There had been some nausea but no vomiting. About February 1, she grew worse, was somewhat excitable for a few days, and then became dull and drowsy, with staring eyes, and talked very little. When admitted to the Swedish Covenant Hospital, February 9, the temperature was 99.4, pulse 110, and respiration 34. On the following day the temperature ranged from 98.8 to 100; the pulse, from 114 to 122. Her face had a dull expression and there was slight facial palsy on the right side. The protrusion of the tongue was weak. The back was somewhat rigid. The tendon reflexes in the left arm and leg were stronger than those of the right side, but there was no rigidity of the extremities. The pupils and eyegrounds were normal. Sensation was normal. Mentally the patient was dull, slightly confused and disoriented for time. She grew worse. February 12, the temperature rose to 102, and on the 13th it ranged from 103.2 to 105.6, with a pulse rate of 140 to 150. Toward evening, she developed a marked respiratory difficulty with signs of pulmonary edema, and died.

Necropsy.—This was held, eleven hours after death, by Dr. B. O. Raulston, who made the anatomic diagnosis of: Marked edema and hyperemia of the lungs; hyperemia and cloudy swelling of the heart muscle, liver and kidneys; marked generalized cyanosis; pregnant uterus—about the seventh month. Extensive petechial hemorrhages in the visceral pleura, the epicardium, the renal pelves, the urinary bladder and the stomach, in both the mother and the fetus; mild tracheitis and bronchitis; acute hyperplasia of the spleen; edema and hyperemia of the brain; blood-stained, frothy fluid in the mouth and nose; mild atheromatous sclerosis of the aorta; slight edema of the ankles; edema and bluish discoloration of the external genitalia; lactating mammary glands; redundant sigmoid; cholelithiasis; healed calcified tuberculous tracheobronchial lymphadenitis; fenestrated thebesian valve and membranous eustachian valve; retrocecal appendix.

After formaldehyd hardening of the brain, the pia showed marked congestion and engorgement of the veins, but there was no exudation. The brain itself was distinctly edematous, as shown by the even, semicircular outline of the cut surfaces after formaldehyd hardening. The gyri were swollen and flattened, and the sulci narrow and compressed. The cut surfaces showed marked congestion, especially in the white matter of the centrum ovale and the basal ganglions. Minute hemorrhages were made out in these regions, as well as in the upper part of the pons. In the cerebellum the congestion was relatively less striking. The ventricles and their ependyma were of normal appearance.

Sections from the congested portion of the white matter of the left frontal lobe showed marked distention of the vessels, particularly the veins, but there were only very small lymphocytic infiltrations around some of the smallest vessels. In only a few places were any extravasations of blood to be seen, and these were of small size. The number of leukocytes in the lumen of the congested vessels was small with the exception of one small vein, cut longitudinally, which contained a fresh thrombus consisting of shadows of red cells and leukocytes, about half of which were observed to be polymorphonuclear.

In the left motor cortex the pia was very loose in texture, with slight increase in cells, and there was no definite sign of inflammation in the cortex itself.

The left optic thalamus showed very extensive inflammation, with large collections of mononuclear cells about the distended vessels, large and small (Fig. 1). No large hemorrhages were seen. In the right corpus striatum a similar condition prevailed (Fig. 2).

Sections made at three levels of the pons all showed very marked inflammatory change which was most pronounced in the dorsal portion (Fig. 3). Throughout the pons, small hemorrhages were numerous. The largest one encountered is shown in Figure 4.

Sections of the bulb, made at two levels, failed to show any inflammatory changes.

No organisms were found in sections from the regions mentioned, stained by the Gram-Weigert method.

Case 3.—*History.*—A girl, aged 13 years, first seen, February 14, with Dr. L. W. Sauer, had complained, February 1, of buzzing in the ears and soreness in the jaws, so that mumps was at first suspected. A few days later, the eyes and throat became red; the temperature rose to 102, February 10, and influenza was suspected. The patient had no headache, and was unusually drowsy toward evening. The leukocyte count, February 11, was 12,200, and February 13, 11,800. February 11, the tongue seemed thick and the speech became indistinct. There began to be difficulty in swallowing on the 13th.

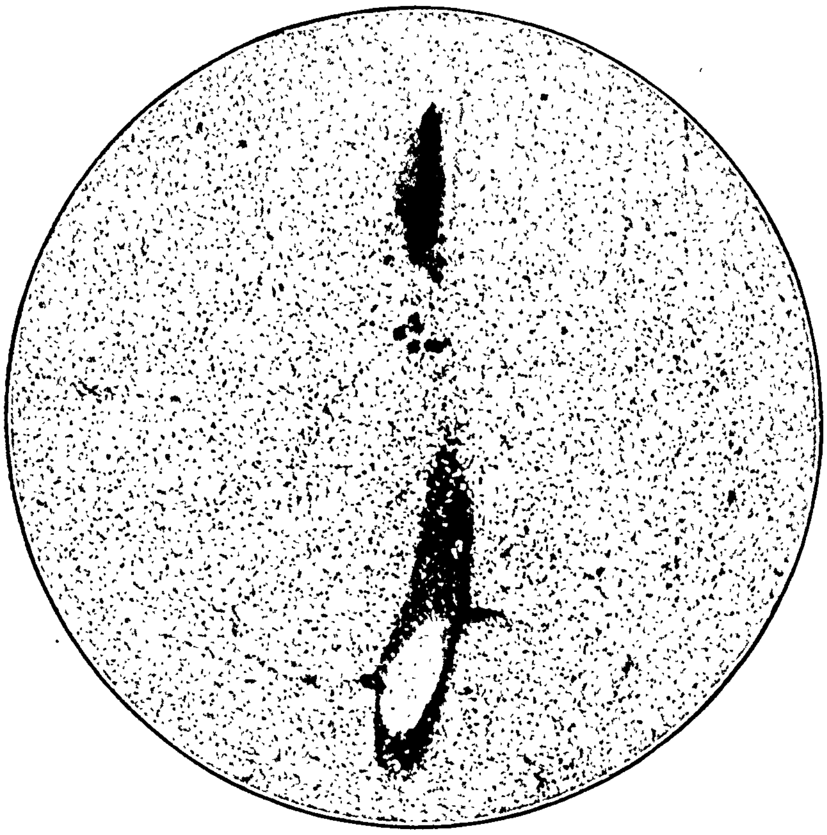

Fig. 3 (Case 2).—Pons: round cell infiltration and hemorrhage about vessel cut longitudinally; × 54.

Examination.—The patient was very drowsy and listless, with immobile face and a peculiar fixed puckering of the lips, which persisted. There was slight bilateral facial weakness. The tendon reflexes were increased, more so in the left leg, and there was suggestion of a left Babinski sign. Lumbar puncture was made, and although there was considerable difficulty in entering the canal, the patient seemed to pay no attention. The fluid was under normal pressure, with a slight accidental admixture of blood. A second puncture yielded a clear fluid with the cell count of 7. No organisms were obtained in smears or cultures. Blood cultures were also negative.

Clinical Course.—The patient was taken to the Evanston hospital the same day and gradually grew worse, with increasing rigidity of the entire body. Nystagmus became a marked feature. From February 17 on she was unable to swallow and had to be fed by nasal tube. The temperature during the first week in the hospital ranged from 99 to 100 and the pulse from 100 to 120, but on February 20 the temperature reached 101.2 and on the 23d, 103. The lethargy was more pronounced, but consciousness was retained. On the 23d a left Babinski sign was obtained, and the left extremities were more rigid than the right. The abdominal reflexes were present. During the following two weeks there was very little change. The temperature was practically always between 100 and 101, and the pulse between 120 and 140. The head was constantly kept turned to the right. Every day the patient had attacks of jerkings in the extremities, together with profuse perspiration and usually some irregularity of the pulse. She could not talk, swallow or open the mouth, but seemed to understand everything and followed an object with her eyes. The muscular rigidity resembled that of a cataleptic state and could be somewhat overcome by passive movement.

For the first two weeks she had to be catheterized, and during this time constipation was so extreme that even nine drops of croton oil and enemas were unsuccessful. Later the urine was voided involuntarily, and the bowels readily moved by enema.

Case 4.—*History.*—A married woman, aged 44, seen with Dr. Rufus Stolp, Feb. 15, 1919, had always enjoyed good health; but early in January she had some indisposition with fever for which, however, she did not consult a physician. She never was quite well from this time on, and after the middle of January she gradually grew listless, weak and unsteady, with a tendency to stiffness of the extremities and dragging of the right foot in walking.

Examination.—When seen, February 15, the patient was sitting in a chair with an absolutely listless, expressionless facial appearance, the eyes being half closed. She was clear mentally, but volunteered no remarks and answered questions only in monosyllables. The temperature was normal, but the pulse rate was 132. In addition to partial ptosis, there evidently was decided weakness of the facial muscles on both sides. The shutting of the left eye was particularly weak; otherwise there was no definite paralysis. The arms and legs were moderately stiff, the stiffness being more pronounced on the right side. The tendon reflexes were practically normal, and there was no Babinski sign. When a lumbar puncture was made, the patient was utterly indifferent and gave no expression of any discomfort. The fluid was clear and under normal pressure.

Laboratory Tests.—The Wassermann test with the blood was weakly positive with the cholesterinized antigens. The spinal fluid gave a negative Wassermann test, cell count 9, and very weakly positive Nonne-Apelt globulin test and Lange coloidal gold test (1221110000).

Dr. Stolp kindly informed me that the patient's condition at first remained unchanged, then grew slowly worse with increasing stiffness of the extremities and coarse jerkings on attempted movement. There was no special difficulty in talking or swallowing. The bowels were obstinately constipated; February 21, retention of urine set in. February 23, when broth was fed to her with a spoon, she suddenly choked. Up to this time she had been clear mentally and had talked fairly well. She rapidly developed signs of pulmonary edema, and died in two hours.

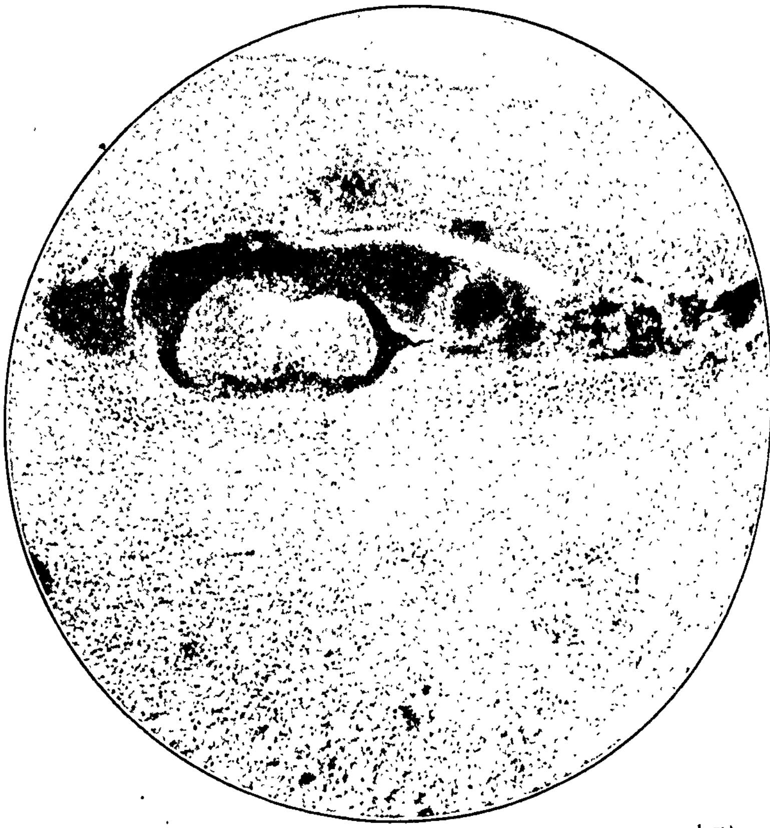

Fig. 4 (Case 2).—Pons: large hemorrhage about vessel near ependyma of fourth ventricle; × 60.

Necropsy.—This was held four hours after death by Dr. B. O. Raulston, who made the anatomic diagnosis of edema and hyperemia of the brain; moderate edema and hyeremia of the lungs; hyperemia of the liver, spleen and kidneys; petechial hemorrhages in the visceral pleura, the epicardium, the lining of the stomach and renal pelves; moderate reddening of the lining of the trachea and main bronchi; atheromatous patches in the lining of the abdominal portion of the aorta; small cysts of the left ovary.

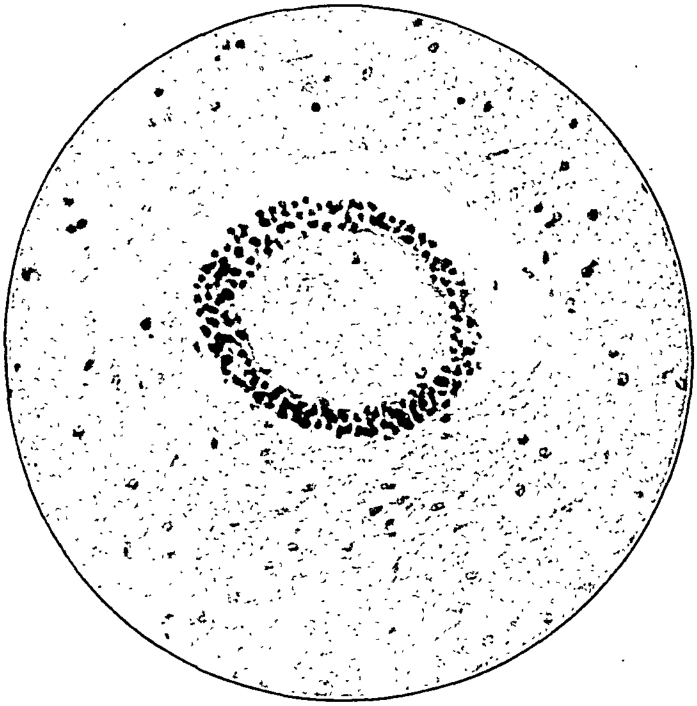

Fig. 5 (Case 4).—Corpus striatum: infiltration of mononuclear cells around distended vein; × 280.

After formaldehyd hardening of the brain, the meninges showed no changes except hyperemia. The general appearance of edema was present. Considerable hyperemia was apparent on the cut surfaces, especially in the region of the basal ganglions and the pons. The subthalamic region was the one most affected. The cerebellum showed no marked change.

Histologic examination of the frontal and parietal lobes detected no signs of inflammation in the pia or the cortex. In the occipital lobe there was slight lymphocytic increase in places, but no distinct infiltrations. In the sulci the pia and adjacent cortex were very edematous. The optic thalamus showed distended vessels surrounded by accumulations of mononuclear cells. The lenticular nucleus showed distinct but less intense inflammation (Fig. 5). The crus cerebri showed a much more intense inflammation, with very large and numerous cell infiltrations (Fig. 6). The midbrain at the anterior end of the aqueduct also showed marked inflammation (Fig. 7). Throughout the pons, especially the dorsal portion, there were intense congestion, hemorrhagic areas and perivascular infiltrations, but the latter were less conspicuous than in the midbrain and basal ganglions. In the bulb, well marked congestion and inflammation were present, especially dorsally, in the region of the vagus nuclei (Fig 8). No bacteria were seen in sections stained by the Gram-Weigert method.

CASE 5.—*History.*—A man, aged 40, admitted to the Presbyterian Hospital, Feb. 20, 1919, from his home in Iowa, had begun, February 9, to complain of diplopia, which lasted only two days, but he felt ill and on the 14th summoned a physician, who found that his temperature was 103. It was 102 on the 15th and 101.6 on the 16th. On that day, stiffness in the fingers of the left hand and slight difficulty in talking were noted. On the 17th the temperature was normal, but the patient developed retention of urine, and stiffness in the jaws and in the fingers of the right hand. There was no headache nor other pain. He had not been constantly confined to bed until admitted to the hospital.

Examination on Admittance.—The patient was listless and very quiet, but clear. He kept the eyes half closed and did not volunteer any conversation or movement. The neck was quite stiff; the pupils and eyegrounds were normal; there was no ocular paralysis. There was apparently bilateral facial weakness, as the eyes could not be firmly closed or the teeth shown, nor could the patient whistle. The jaw was stiff, but with great effort the patient could separate the teeth about 3 cm. In biting, the muscles of mastication seemed to be weak. The tongue was tremulous and could not be protruded beyond the lips; there was no atrophy. The arms and legs were rigid, more so on the left side, but they could be fairly well relaxed by passive movements. The patient could move all the extremities but did so very slowly, with apparently great effort, and in a jerky manner, the effort resembling that of a catatonic patient. There was a constant tendency to hold the finger tips close together and slightly overlapping, with partial flexion at all joints. When he folded his arms on his chest they showed coarse jerkings, and when he sat up with the arms across the chest he was able to raise the head only a few inches. With the aid of the hands he could sit up, but the effort resulted in a coarse tremor in the muscles of the arms, trunk and the left leg. All of the tendon reflexes were moderately increased, without clonus. The plantar and abdominal reflexes were normal. Sensation was normal.

Lumbar puncture revealed a clear fluid under moderately increased pressure. The Wassermann test was negative. The cell count was twenty-six (mononuclear cells). The Nonne-Apelt globulin test was weakly positive; the Lange colloidal gold test gave a weak reaction (0112111000). The Wassermann test with the blood was also negative.

Blood examination revealed: hemoglobin, 80 per cent.; red cells, 3,840,000; white cells, 9,200.

Clinical Course.—During the following days the general rigidity and tendency to jerkiness on any attempted movement increased. There was a typical "cog wheel" resistance on passive movement of the elbows. The patient remained clear but extremely listless. The speech became more unintelligible, but he had no difficulty in swallowing until a few days before death.

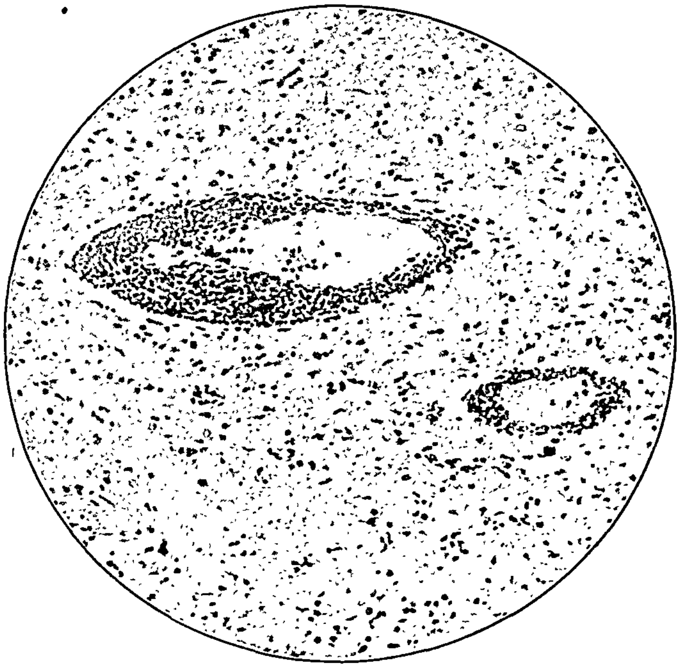

Fig. 6 (Case 4).—Right crus cerebri: dense perivascular cell infiltrations; × 60.

Though the stupor increased, the patient did not sleep well, waking up frequently during the night. February 24, drooling became marked and the breathing labored, but examination of the chest was negative. Perspiration became profuse and an extensive sudaminal rash appeared. After March 1, catheterization was not necessary, as the urine was voided involuntarily. A second lumbar puncture, March 3, also yielded a clear fluid, with a cell count of 20, and weakly positive Nonne and Lange tests. Cultures of blood and spinal fluid were made by Dr. Ruth Tunnicliff both by aerobic and anaerobic methods, but no growth was obtained. From February 20 to the 24th the temperature varied from 98 to 100.6 F., but from that time on it gradually rose, reaching 102, February 28, 104, March 2, 105, March 6, and 107, 6 a. m. March 8. The pulse rate showed a corresponding increase, being generally 120 until March 2, and after that from 120 to 140. The respirations showed similar behavior and were from 36 to 48 a minute after March 1. After March 4 there were frequent attacks of dyspnea and choking. In the afternoon of March 8 the pulse became imperceptible, the respirations very shallow and cyanosis marked. The patient died at 5:30 p. m. Necropsy was refused.

Case 6.—*History.*—A married woman, aged 42, seen Feb. 24, 1919, with Dr. Yorke B. Sutch, previously had been well except for migraine. Her husband had influenza in October, 1918, but she escaped. At Christmas time she began to complain of occasional tinnitus; otherwise she was well until about February 1, when she consulted Dr. Sutch on account of shortness of breath and a rapid pulse. She went to bed the next day, and for a few days the temperature went up to 102. Then indistinctness of speech and difficulty in swallowing set in. The temperature was rarely above 100, but the pulse rate was from 110 to 120. She perspired considerably at night, and occasionally complained of pain in the left calf; and the left leg became a little rigid. There was marked tremor in the tongue and a little in the hands. From February 8 on, she had to be catheterized every day. February 15, lumbar puncture was made. The fluid was clear, under normal pressure. It contained 25 lymphocytes per cubic millimeter, and gave a positive Nonne globulin test and an almost negative Lange test. The Wassermann test was negative with both blood and spinal fluid.

Examination.—When I saw the patient, February 24, the temperature was 99.6, pulse 110, respiration 38. She was clear mentally. There was no distinct ocular palsy, but movements of the eyes could apparently be made only with great effort. There was weakness of the facial muscles of both sides, more on the right. The tongue was tremulous and could be protruded only a short distance. There was considerable general muscular rigidity, most marked in the left leg; but the tendon reflexes were normal as well as the plantar reflexes. Sensation was normal. Within a few days she began to improve. Swallowing became better and the urine was voided normally. The most troublesome symptom was the coarse, almost choreic jerkings in the left leg. This condition always yielded temporarily to hypodermics of scopolamin. The temperature remained below 99, but the pulse rate at the time of the last communication from Dr. Sutch, March 17, continued to be rapid, up to 120.

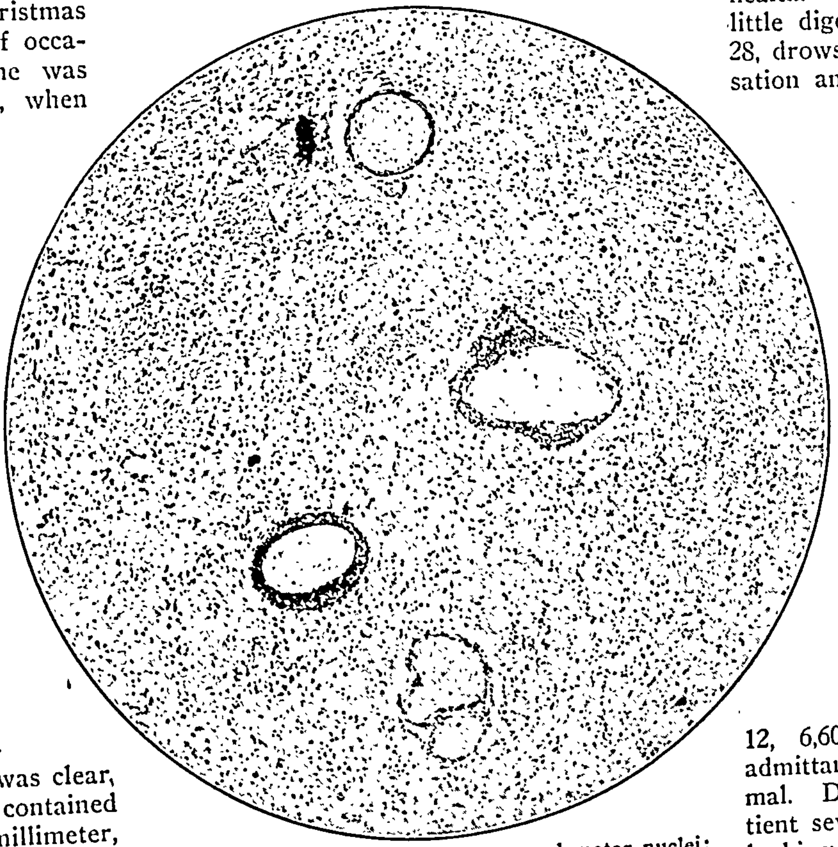

Fig. 7 (Case 4).—Midbrain near oculomotor nuclei: cell infiltration about the engorged vessels; × 60.

Case 7.—An unmarried woman, aged 34, seen at the Evanston hospital, March 11, 1919, with Dr. Rufus Stolp, ten days previously had felt feverish and complained of double vision. On the 8th she had made a trip to Chicago to have her eyes examined. On admittance to the hospital on the 11th, the temperature was 99.6, pulse 80, respiration 24. She was conscious, but very lethargic and with a dull facial expression. There was no definite ocular palsy, but the eye movements were slow. The eyegrounds were normal; there was no nystagmus. There was only slight rigidity of the neck and arms, but the legs were very decidedly rigid. They showed only slight increase in the tendon reflexes and normal plantar reflexes. The abdominal reflex was not obtained in the left lower quadrant, and was weak in the other quadrants. Sensation was normal.

The spinal fluid gave a negative Wassermann test but showed slight increase in globulin. No cell count was made.

March 12, the lethargy was more marked and the arms and neck were more rigid. The temperature ranged from 98 to 101. The patient had to be catheterized nearly every day and grew duller and stiffer until March 16. When examined on that day, she was considerably brighter, and the rigidity in the legs was diminished and that in the arms was very slight. The tendon reflexes were normal.

Case 8.—A man, aged 62, seen, March 13, 1919, with Dr. E. F. Wells, for ten years had shown symptoms of intermittent claudication of the legs, but otherwise had been in good health. Early in January, he had a little digestive disturbance. January 28, drowsiness set in, with dizzy sensation and slight unsteadiness. The eyes became sensitive to light, and on February 5, lateral diplopia appeared which lasted one day and later recurred at times. He also complained of slight respiratory distress, a little trouble in talking, drooling and, during the last two days, incontinence of urine. He had not been confined to his bed prior to admittance to St. Luke's Hospital, March 10. March 11, lumbar puncture revealed the fluid clear, Wassermann test negative, globulin test positive, cell count 4. The blood gave a negative Wassermann reaction. March 10, there was a leukocyte count of 4,800 and on March 12, 6,600. The temperature after admittance to the hospital was normal. During the interview, the patient several times saw double when looking to the right. He appeared alert and talked freely. The abdominal reflexes and the left knee and ankle reflexes were not obtained. The arm reflexes were normal. There was no definite paralysis. Sensation was normal.

March 22, Dr. Wells reported that the patient had become somewhat dull mentally, and that his legs had grown weaker. Otherwise, no new symptoms had developed.

Case 9.—A married woman, aged 34, seen at the Evanston hospital, March 12, 1919, with Dr. C. A. Aldrich, was said to have been somewhat anemic but otherwise well until March 3, when she felt weak and developed retention of the urine. She had a smothering sensation, and the eyes were sensitive to light. The temperature during the following days ranged from 99.4 to 100.4. The leukocyte count was 8,800. She generelly lay with the eyes half closed, and spoke only to answer questions. Blueness of the fingers was noted after the third day.

When the patient was examined, March 12, she was dull and drowsy, but answered questions without any special difficulty. The jaw was rather stiff, and the teeth could not be separated more than 2 cm. The neck was also slightly stiff, but the head could be turned about without pain. The knee and ankle reflexes were weak. The elbow reflexes were not obtained; the wrist reflexes were elicited only on the left side; the plantar reflexes were normal. The temperature was 101.

When seen again, March 16, the patient was brighter and showed no rigidity, but felt too tired to sit up long enough to try to urinate, and still had to be catheterized every day. The temperature since the 12th had usually been 99.5. Both wrist reflexes were now obtained as well as the right elbow reflex. The tendon reflexes in the legs were normal.

Case 10 presents both features of encephalitis and a confusional psychosis.

Case 10.—A man, aged 39, seen at the Caledonia (Minn.) hospital, March 6, 1919, with Dr. W. S. Browning, two and a half weeks previously, when feeling tired and nervous, had left his home in Illinois for a visit in Minnesota. After a few days, he became more tired, said he had no energy, and complained of poor sleep. He began to complain of backache and blurring vision: he said he could see better with one eye closed. February 26, he became confused and irrational. He was admitted to the hospital, March 2, with temperature 103, pulse 70, and respiration 16. From that time on the temperature gradually declined, and was 99.6, March 6. Most of the time he was in a state of muttering delirium and talked continually. On the morning of March 6, he was less delirious but rather drowsy.

When examined in the afternoon, March 6, he answered questions fairly promptly, but was disoriented as to time and place. There was no speech disturbance, but a slight weakness of the left external rectus was present. There was no other cranial nerve palsy. The strength in the extremities was good, and there was no rigidity. The right abdominal reflex was not obtained. The wrist, elbow, knee and plantar reflexes were normal; the ankle reflexes were moderately increased. Lumbar puncture yielded a clear fluid with negative Wassermann reaction, cell count 9, and Nonne globulin test weakly positive. The Lange gold test gave a weak but distinct reaction (0122110000).

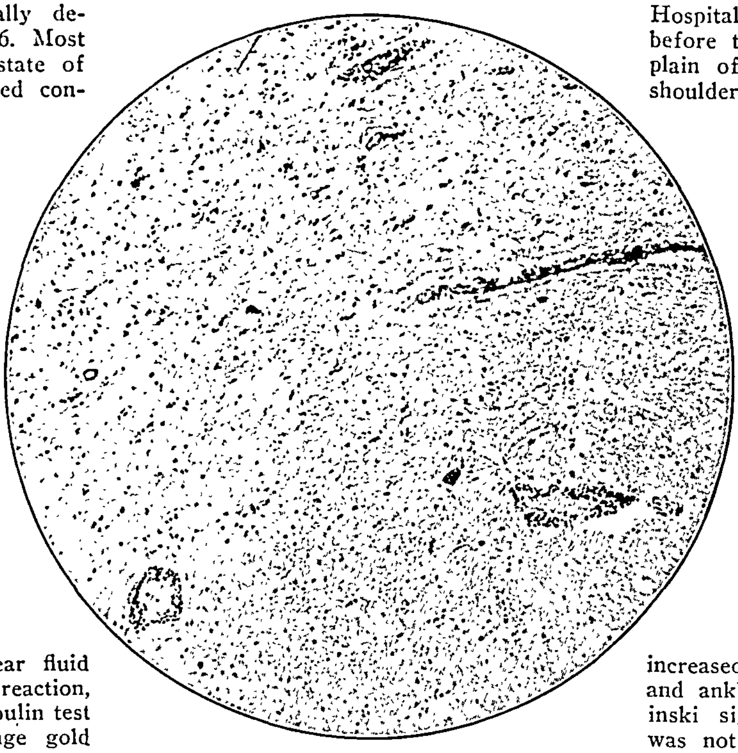

Fig. 8 (Case 4).—Lower bulb: perivascular infiltrations; × 90.

March 18, Dr. Browning reported that the patient's general condition had somewhat improved. His orientation was good. There was no more diplopia, but slight unilateral facial paralysis existed. The maximum daily temperature was 100. The patient was still inclined to be somnolent, but could easily be aroused.

Case 11 differs from the others by the absence of somnolence after the first few weeks, and the presence of violent choreiform jerking limited to one extremity.

Case 11.—A woman, aged 33, seen, March 9, 1919, with Dr. W. K. Harrison, about January 20, after having felt tired for a week, had been suddenly taken ill with sore throat and fever, her temperature reaching 103. January 21, she became extremely drowsy, and on the next day delirious, giving voice to many absurd delusions, among them the idea that her left leg was not her own but belonged to her niece. During the first week, blisters containing bloody fluid appeared on both heels. By the middle of February the fever and somnolence subsided, and the chief trouble from now on consisted of irregular, jerky movements in the left lower extremity, beginning in the toes and involving the whole limb after three or four days. The movements ceased entirely during sleep. Headache, visual disturbances and sphincter disturbances were absent.

March 10, she was admitted to my service at the Presbyterian Hospital.

Neurologic examination was practically negative, except for continuous choreic movements of large amplitude in the left leg. On making lumbar puncture, a clear fluid under moderately increased pressure was obtained. It gave a cell count of 10, a weakly positive Nonne-Apelt globulin test, and a weak colloidal gold reaction (1222110000). During the following ten days the choreic movements became less severe. Scopolamin hydrobromate and sodium cacodylate were administered.

While none of the previous patients gives a history of a definite attack of influenza, such a history was obtained in Case 12, which, however, is not one of the lethargic, or brain stem, type of encephalitis but of the hemispheral variety.

Case 12.—A boy, aged 14 years, had had an attack of influenza one month prior to admittance to the Presbyterian Hospital, Dec. 5, 1918. Ten days before this date, he began to complain of pain in the left arm and shoulder. When he came to the hospital it was found that his temperature was 101, and a diagnosis of a second attack of influenza was made. The attack was mild, and on December 11 he was transferred to my service on account of the trouble with the left arm, which had grown a little better during his stay in the influenza ward. He showed no somnolence. The right pupil was larger than the left; there was no external ocular or other cranial nerve palsy. The movements of the fingers of the left hand were relatively weak; the strength in both legs was good. The tendon reflexes were increased in the left leg, with knee and ankle clonus and positive Babinski sign. The abdominal reflex was not obtained on the left side. The wrist and elbow reflexes were not obtained on the left side. The spinal fluid was entirely normal. The cell count was 5, globulin negative. The condition of the patient rapidly improved, and he was discharged, recovered, January 19.

30 North Michigan Avenue.

Polyneuritis on a Cooked Lean Meat Diet.—Voegtlin and Lake of the United States Public Health Service have conducted some experiments with animals to study the nutritive value of meat subjected to the temperatures ordinarily used in cooking with reference to producing polyneuritis on account of the destruction of the antineuritic vitamin. Polyneuritis was produced in cats and dogs as the result of an exclusive dietary of lean beef which was heated for three hours at 120 C. in the presence of alkali (sodium carbonate). The symptoms produced were those characteristic of beriberi. Administration of the antineuritic substance of yeast was followed by the prompt disappearance of the symptoms. Exposure of the beef for three hours to a temperature of 120 C. without the previous addition of the alkali does not completely destroy the antineuritic power of this food. It is therefore concluded that the ordinary preparation of meat for human consumption does not lessen its food value in this respect.

INFLUENZA OCCURRING IN PREGNANT WOMEN

A STATISTICAL STUDY OF THIRTEEN HUNDRED AND FIFTY CASES *

JOHN W. HARRIS, M.D.
BALTIMORE

In the latter part of October, 1918, when the epidemic of influenza was at its peak in this locality, the seriousness of the disease as seen in pregnant women caused considerable alarm among those in charge of obstetric cases. It soon became apparent that there was a great diversity of experience as regards the mortality, some of the practitioners losing most of their cases, others very few. In addition to its importance in contributing toward a more definite knowledge concerning the prognosis of influenza in pregnant women, it has seemed to me that a statistical study based on a large number of cases would also be of value in showing the effect of the influenza on the course of pregnancy. Owing to its severity and wide occurrence, and to the fact that it was especially prevalent among young women of the child-bearing age, the epidemic offered the best opportunity we have perhaps ever had to study the extent to which the progress of pregnancy is interfered with by an acute, severe, infectious disease.

With these purposes in view, a questionnaire was prepared which included data as to race and age of the individual patient, the month of pregnancy, character of the attack (whether mild or severe, and whether complicated by pneumonia), recovery or death of the mother, and whether or not pregnancy was interrupted. Copies of this blank were sent to all of the physicians of the state of Maryland, and also to the members of the American Gynecological Society, the American Association of Gynecologists and Obstetricians, and the local obstetric societies in four of the larger cities. I wish here to express my appreciation of the ready response on the part of the physicians who replied, and of the careful manner in which they supplied the information desired.

Of the total number of cases returned, 1,350 were reported in full detail, and it is on these that our statistics have been based. Other cases were reported but were not used, owing to incompleteness of the data in some particular respect. Of the 1,350 cases, 971 were from the state of Maryland, and hence the great majority occurred under the same general conditions. In race the patients were predominantly white, the proportion being 1,266 white, eighty-two negro, and two Japanese. Since in most instances the duration of pregnancy was expressed in calendar months, the same method has been followed in this paper.

The results of this study are given herewith in the form of a series of tables in which the statistics are presented so as to show their relation to the various aspects of our problem. By a comparative study of these tables important data are revealed, both as regards the course of influenza in pregnant women and the effect of the influenza on the course of pregnancy. No conclusions can be drawn, however, as to whether the incidence of influenza is greater among pregnant women than among nonpregnant women or men of the same age. This question cannot be determined until we have reliable statistical data concerning influenza in general. Our own figures show only what happened in this group of 1,350 patients.

TABLE 1.—INCIDENCE OF PNEUMONIA AND PERCENTAGE OF MORTALITY IN CASES OF INFLUENZA REPORTED FOR THE DIFFERENT MONTHS OF PREGNANCY

Month of Pregnancy	Uncomplicated by Pneumonia			Complicated by Pneumonia				Total Cases	Gross Mortality
	No. of Cases	Recovered	Percentage of Mortality	No. of Cases	Recovered	Died	Percentage of Mortality		
1	12	12	0	2	1	1	50	14	7

Total	672	672	0	678	313	365	54	1,350	27

As regards the course and prognosis of influenza in pregnant women, we may draw certain general conclusions from Table 1. Our first observation is that about one half of all the patients developed pneumonia, and of these about 50 per cent. died, giving a gross mortality of 27 per cent. In those developing pneumonia, the mortality was somewhat higher in the last three months of pregnancy. From Table 1 it will be seen that the largest number of cases were reported for the sixth, seventh and eighth months, and fewer from the third to the fifth months. As to the first two months, we must assume that in many instances the existence of pregnancy was not suspected by the attending physician, and thus such cases would not be included in the reports. On the other hand, we may well reason that cases from the later months were likely to be reported, pregnancy being then more obvious. This would explain the larger number of

---

*From the Johns Hopkins Hospital and Carnegie Laboratory of Embryology.

cases reported for that time. We may safely conclude that the individual is no more susceptible to the disease at any one month of pregnancy than at another.

As regards mortality, the percentage is distinctly higher in the last three months of pregnancy. Sixty per cent. of the cases developing pneumonia in those months proved fatal; in the ninth month it reached its highest point, 61 per cent. When considered as gross mortality the percentage is reduced somewhat, owing to the large number of cases reported for this period.

The effect of influenza on the course of pregnancy is shown in Tables 2, 3 and 4, in which the frequency of coincident abortion or premature birth is tabulated according to the severity of the influenza. In the 626 cases uncomplicated by pneumonia the pregnancy was interrupted in 26 per cent., the ratio being somewhat higher in the first three months. This figure is not greatly in excess of the frequency one would expect under ordinary conditions. Moreover, it is to be remembered that many of these abortions might have occurred in the absence of the disease, or at least that the disease may have served only as a terminal factor in bringing about the abortion of an ovum already pathologic. In the cases complicated by pneumonia, the frequency of interruption of pregnancy is doubled, being 52 per cent. in 585 cases. If we disregard the first two months, the percentage is still higher, termination of pregnancy occurring in 62 per cent. of 308 cases. In view of the popular opinion that the presence of influenzal pneumonia nearly always causes an interruption of pregnancy, it is of interest to note the surprising fact that in 38 per cent. of the fatal cases cases the patients died without interruption of pregnancy. This would indicate that when the ovum and the placentation are normal, an extremely severe disturbance in the condition of the mother may be required in order to bring about the termination of pregnancy.

TABLE 4.—FREQUENCY OF INTERRUPTION OF PREGNANCY IN FATAL CASES

Month of Pregnancy	Number of Deaths Reported	Pregnancy Uninterrupted		Pregnancy Interrupted	
		No.	Per Cent.	No.	Per Cent.

7............	152	28	18	83	39	47
8............	119	20	13	111	44	40
Total......	743	117	16	468	191	41

The reverse of Table 4 is presented in Table 5, in which the data are so arranged as to show the effect of abortion and premature labor on the incidence of mortality. In 743 patients in whom pregnancy was not interrupted, there was a mortality of 16 per cent. In 468 cases in which there was termination of pregnancy, the mortality was 41 per cent. This distinctly higher percentage is consistent throughout the different stages of pregnancy with the exception of the first two months; but, as already pointed out, the number of cases in those months is too small to warrant any definite conclusions. It is plainly evident that the interruption of pregnancy renders the prognosis more grave. If we restrict our data to the cases that were complicated by pneumonia, it is found that in the 383 cases in which pregnancy was not interrupted, the mortality was 41 per cent.; whereas in 395 cases in which pregnancy was interrupted there was a mortality of 63 per cent.

It may be of interest to present the same statistics in another form, which has certain advantages from the point of view of accurate comparisons. One can calculate the mathematical probability of certain types of occurrence in the general "universe of discourse" comprehended by these statistics. By elementary theory of probability, it is known that if an event may happen only in one or the other of two ways, a and b, and in n trials it actually happens m times in one particular way, a, then the probability (p) of its occurrence in that way may be thus expressed: $p = \frac{m}{n}$, and the probability (q) of its occurrence in the other way, b, would be expressed $q = 1 - p$.

Applying this principle to the present statistics, and grouping the material, we get the results shown in Tables 6, 7 and 8, and in the chart, which have been prepared for me through the kindness of Dr. Raymond Pearl of the School of Hygiene and Public Health.

From these tables we note that, so far as may be judged from the present statistics, the chances of the interruption of pregnancy are about doubled if the woman contracts both influenza and pneumonia, over what they are if she has influenza alone. It is the general impression of obstetricians that normally, and without known complications, the chance is about 1 : 5 that pregnancy will be interrupted. The data in Table 6 indicate that the normal chance of the interruption of pregnancy is not greatly increased by the presence of influenza alone. The chance of death from influenza complicated by pneumonia is obviously greatly increased by the interruption of pregnancy.

TABLE 6.—DEGREE OF PROBABILITY THAT THE PREGNANCY OF A WOMAN WHO CONTRACTS INFLUENZA UNCOMPLICATED BY PNEUMONIA WILL BE INTERRUPTED

If the Influenza Attack Is in the:	Probability of Interruption	Chance of Interruption Is One in:
First third of pregnancy....................	0.390 ± 0.03	2.6
Middle third of pregnancy..................	0.212 ± 0.018	4.7
Seventh and eighth months of pregnancy	0.254 ± 0.018	3.9

As this paper was about to be submitted for publication, two others appeared, dealing with the statistical relation of influenza to pregnancy. Bland[1] reports 337 cases. In a study of 200 of these he gives a mortality of 49 per cent. This is somewhat higher than is yielded by our larger number of cases in which, as has been seen, we have a total mortality of 27 per cent. As to the effect of the disease on pregnancy, Bland reports the interruption of pregnancy in 58 per cent. of his cases, a figure considerably higher than that shown by our data, which is 39 per cent. in 1,211 cases falling within the first eight months.

TABLE 7.—DEGREE OF PROBABILITY THAT THE PREGNANCY OF A WOMAN WHO CONTRACTS INFLUENZA AND PNEUMONIA WILL BE INTERRUPTED

If the Influenza Attack Is in the:	Probability of Interruption	Chance of Interruption Is One in:
First third of pregnancy....................	0.644 ± 0.032	1.6
Middle third of pregnancy..................	0.429 ± 0.021	2.3
Seventh and eighth months of pregnancy	0.561 ± 0.022	1.8

Attention may also be called to the paper of Kosmak,[2] in which is given a summary of twenty-one hospital cases studied by him, in addition to several private cases. This author has kindly permitted me to use his data, and they are incorporated in the foregoing statistics.

TABLE 8.—DEGREE OF PROBABILITY THAT A PREGNANT WOMAN WHO CONTRACTS INFLUENZA AND PNEUMONIA WILL DIE

If the Influenza Attack Is in the:	Probability of Death	Chance of Death Is One in:
First third of pregnancy....................	0.505 ± 0.034	2.0
Middle third of pregnancy..................	0.483 ± 0.021	2.1
Last third of pregnancy and at term.....	0.595 ± 0.019	1.7

RESULTS OF THE STUDY

It is assumed that the 1,350 cases on which these statistics are based were serious enough to require medical attention, and do not include the very mild cases; nor do they include many of the cases falling within the first two months of pregnancy, when gestation might easily escape the knowledge of the physician. With these reservations, the results of the study are as follows:

1. Pneumonia complicated the influenza in about one half of the pregnant women here reported.
2. In the cases complicated by pneumonia, about 50 per cent. of the patients died, the mortality being somewhat greater during the last three months of pregnancy.
3. The gross mortality of all cases was 27 per cent.
4. Pregnancy was interrupted in 26 per cent. of the uncomplicated cases, and in 52 per cent. of the cases accompanied by pneumonia. In the cases ending fatally, abortion or premature labor occurred in 62 per cent. Thus, in 38 per cent. of the fatal cases the patient died without interruption of pregnancy.
5. The mortality of influenza was considerably higher (41 per cent.) in the cases complicated by abortion or premature labor than in those in which pregnancy was uninterrupted (16 per cent.).

INFLUENZA IN A NEWLY BORN INFANT

REPORT OF A CASE

ISAAC A. ABT, M.D.

CHICAGO

Through the kindness of Dr. David S. Hillis of the Chicago Lying-In Hospital, I was permitted to examine a newly born infant whose mother showed symptoms of influenza one day previous to labor. In order to make clear the condition of the baby, I will include the history of the mother's illness, furnished by Dr. Hillis.

REPORT OF CASE

History.—Mrs. J., aged 26, a primipara, developed symptoms of influenza late in the afternoon of December 27, when she was within two weeks of term. The symptoms were *cough, fever, chilliness, headache and backache, with much* soreness in the chest. She had had no sleep during the night.

Labor pains were first noticed at 6 a. m., December 28. Influenza symptoms continued. At 2:30 p. m. the temperature was 101.2 and the patient was in active labor. The fetal heart tones were more rapid than usual, being 150 throughout labor, but they were always regular and not of a character to indicate mechanical disturbance of fetal circulation. Labor continued normally, and at 12:30 a. m., December 29 the bag of waters appeared at the vulva and was artificially ruptured. The liquor amnii was markedly stained with meconium. At 12:46 there was spontaneous delivery of a boy, whose weight was 6 pounds, 12 ounces.

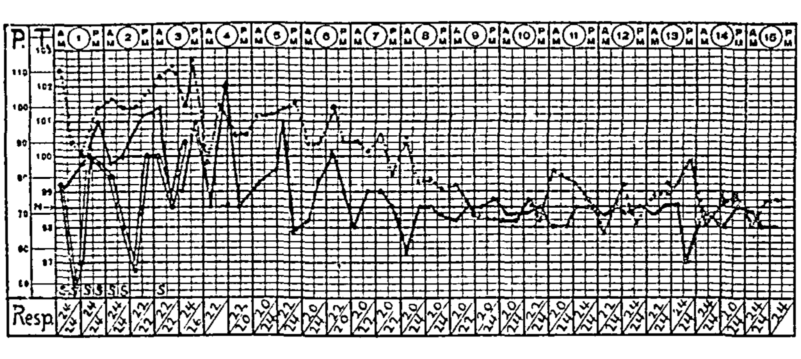
The infant's skin became grayish blue almost immediately after birth, and this condition persisted in spite of vigorous crying and clear air passages. The baby seemed vigorous at birth and breathed promptly after delivery. Auscultation of the baby's chest ten minutes after birth revealed many fine moist râles in both lungs, but there was no dulness on percussion. The following day, Decemb[illegible] 10 a. m., the baby was put to the breast and nurse[illegible] after this, however, the breathing became [illegible] rapid. At 11 p. m. of this day, the respiration r[illegible] perature was not high, never excee[illegible] 97 F. The baby became more and [illegible] tions were superficial and rapid. [illegible] uttered [illegible] cry.

The [illegible] ion of the ba[illegible]'s before [illegible] wed a white[illegible] nucleated red and some large, pale white cells, not classified. The differential count was: polymorphonuclears, 58 per cent.; lymphocytes, large and small, 35 per cent.; large mononuclears, 2.8 per cent., and eosinophils, none.

December 31, the third day of the baby's life, finely crepitant râles were diffusely distributed over both lungs. Cyanosis was marked, and dyspnea extreme. The baby died at 6:05 p. m. with well marked symptoms of bronchopneumonia.

Necropsy.—The following day opening of the thorax revealed minute hemorrhages into the pericardium. The heart muscles were flabby and gave evidence of a parenchymatous myocarditis. On examining the heart valves, one could plainly see a beginning of acute verrucose endocarditis, involving the cusps of the tricuspid valve. Both lungs showed confluent areas of hemorrhagic bronchopneumonia. The spleen gave evidence of an acute splenitis with some edema and passive hyperemia. The kidneys showed no gross pathologic change, and the liver gave the appearaces of cloudy swelling.

Prof. F. Robert Zeit of the Northwestern University Medical School, Chicago, examined the tissues and organs, and reported that "the cultures made from the organs of the baby which were submitted for examination showed many colonies of streptococci. Those made from the lungs showed in addition to the streptococci, which were present in large numbers, a few colonies of *Staphylococcus aureus* and *albus*. Cultures made from the spleen showed a few colonies of *Staphylococcus aureus* and *albus* and many colonies of streptococci. The examination of the organs shows: (1) lung: capillary bronchitis; (2) kidney: glomerulonephritis and necrosis (septic); (3) spleen: acute septic splenitis." Professor Zeit concluded that the cause of death was a streptococcus septicemia.



Pulse (dotted line), temperature (solid line) and respirations of mother after delivery of child; and temperature (double line) of infant after birth; *S*, *S*, stools of infant.

Subsequent History of Mother.—The mother had a mild course of influenza without obstetric or other complications, and left the hospital fully recovered, Jan. 13, 1919.

SUMMARY AND CONCLUSIONS

1. The obstetrician's report indicates that the baby was born prematurely, owing to a maternal influenza.
2. At birth the baby presented symptoms of respiratory infection.
3. The symptoms grew rapidly and progressively worse, leading to the death of the infant on the third day.
4. The necropsy revealed a widely disseminated infection, with minute hemorrhages and a hemorrhagic bronchopneumonia, as well as a septic endocarditis.
5. Streptococci were obtained abundantly from all of the organs examined.
6. We must assume that the baby became infected before birth.

Pain.—Pain is the oldest defense reaction, and potentially painful stimuli are the basis of all primitive reflexes. It is therefore of importance for higher development that these impulses should be rendered less effective in favor of those impressions which lead to more general and discriminative response. But, although they are controlled and even abolished, the mechanism underlying the production of pain must remain in full, physiologic activity, ready to play its part, should occasion arise, in the defense of the body against noxious influences.—Henry Head.

PANDEMIC INFLUENZA IN KOREA

WITH SPECIAL REFERENCE TO ITS ETIOLOGY

FRANK W. SCHOFIELD, D.V.Sc.
AND
H. C. CYNN, M.B.
SEOUL, KOREA

The great influenza pandemic made its appearance in Korea during the month of September, 1918. There seems to be no doubt that the infection came from Europe, via Siberia. The disease spread from north to south along the line of the Southern Manchurian Railway. The first cases seen by us in Seoul, the capital, were during the latter part of September. Before the middle of October the epidemic was at its height. The insanitary conditions of oriental life greatly enhanced the spread of the infection. At present it is impossible to estimate either the number of cases or deaths, as accurate information has not been received from the Japanese authorities. From one quarter to one half of the population must have been affected. Most of the schools were closed, owing to the high incidence among the scholars and teachers. As elsewhere the serious nature of the outbreak was due to the frequent sequelae, bronchitis, bronchopneumonia and heart failure. The symptoms were those of ordinary influenza, but of a more exaggerated type. Headache, and pains and aches in the limbs, with a rapid rise of temperature to 104 or 105 were common symptoms. The temperature usually dropped to slightly above normal within twenty-four hours if the case was uncomplicated. There was also frequent evidence of respiratory infection, which varied from a mild coryza to pneumonia in severity. In some cases there was vomiting and nausea, while in some very acute cases the patient became delirious at the climax of the infection. The symptoms in general corresponded with those reported from other countries.

With regard to transmission of the disease, everything would point to droplet infection as being of paramount importance. Numbers of mild carrier cases, a population of susceptible people, and a disease infecting the upper respiratory passages, causing a prolific secretion of infectious material, produce a combination which must result in a pandemic or widely spread epidemic.

While the number of cases reported are few, the bacteriologic findings are of considerable interest. All were typical cases.

Blood cultures were made from seven patients, and all proved negative.

The sputum was examined in fourteen cases, in three of which the acute symptoms had subsided before this was done. Direct smears were made to bring out the small and lightly staining influenza bacillus. After microscopic examination, a small specimen of the sputum was washed and plated out on blood agar.

Of the fourteen specimens examined, only three showed the presence of Pfeiffer's bacillus. Two of these three cases were complicated with pneumonia. The other eleven cases showed a variety of organisms. Pneumococci prevailed in three, almost pure *Micrococcus catarrhalis* in one, and the others gave a variety of streptococci, gram-negative and gram-positive, diplococci, etc. In two cases a diphtheroid bacillus greatly predominated.

We wish to draw special attention to three particularly interesting cases:

REPORT OF CASES

Case 1.—A man had a typical attack of influenza with no complications. About one month previous to the attack the sputum showed a pure culture of influenza bacilli. The patient had been suffering months from chronic bronchitis. A vaccine was prepared and the patient had received two or three injections of it. Two or three days prior to the attack, the patient, being at that time quite free from influenza, brought a sample of his sputum to the laboratory for further examination. This showed an almost pure culture of the *influenza bacillus*. Sixty hours later the patient was down with typical influenza. The same patient, about two weeks previously, when receiving an injection of influenza bacillus vaccine, stated that his wife and one child were very sick with epidemic influenza, and asked whether it would be possible for him to become infected. I replied that it was more than likely that the present infection and the vaccine would protect him. This patient, whose sputum at times was teeming with the influenza bacillus, had been living with his family for weeks without introducing infection, but to epidemic influenza all succumbed.

Here is a clear-cut case of a person who had carried, and was still carrying, an influenza bacillus infection, and furthermore had received three injections of vaccine (Pfeiffer's bacillus), becoming infected and suffering from an acute attack of epidemic influenza. Had the sputum in this case been examined at the time of attack, only, the case would have been reported as "influenza due to Pfeiffer's bacillus." Some may question whether the organism isolated was the true Pfeiffer bacillus. All we can say is that it possessed all the characteristics of this organism, and was identical with those isolated from other cases.

Case 2.—S., about six weeks before the attack of epidemic influenza, had suffered from acute coryza. Bacteriologic examination of the discharge showed pure growth of a small, irregular, gram-positive bacillus, a sort of diphtheroid. At this time there were no symptoms of influenza. The case was one of simple coryza. Later when the patient suffered from influenza, pronounced coryza developed. This again showed the same small diphtheroid bacillus. The mild laryngitis which developed simultaneously gave a growth of pneumococci.

Case 3.—C. had suffered nine months previously from bronchitis due to the pneumococcus (type not determined). Vaccine treatment had greatly helped the patient, and for six months there had been practically no sputum. After recovery from the acute symptoms of epidemic influenza, a pneumococcal bronchitis remained. It is, of course, impossible to know whether the organism from the first infection had been carried over or not. Vaccine treatment again helped much in clearing up the bronchitis.

EVIDENCE FOR AND AGAINST THE PFEIFFER BACILLUS

It is still questionable whether Pfeiffer's bacillus can be considered as the specific cause of the present pandemic. An endeavor will be made to present evidence both for and against the Pfeiffer bacillus.

Evidence Against the Pfeiffer Bacillus.—1. The highly contagious nature of this disease, frequently spreading, as it does, with lightning-like rapidity, presupposes a virus present in large quantities even in very small specimens of the infected sputum. This we do not find to be the case, assuming Pfeiffer's bacillus to be the cause of the disease.

2. The bacillus is isolated in a comparatively small percentage of cases.

3. The disease attacked one who was at the time infected with Pfeiffer's bacillus.

4. There is an absence of marked antibodies to this bacillus except in cases in which the bacillus has been isolated.

Evidence for the Pfeiffer Bacillus.—1. Pfeiffer's bacillus is found more frequently than any other organism.

2. There is no evidence supporting the theory of an ultramicroscopic cause.

In connection with the question of etiology it seems to us that two mistakes have been made: first, in considering Pfeiffer's bacillus as the specific cause for the disease known to the clinician as influenza, when there is evidence to support the view that clinical influenza may be produced by the pneumococcus or certain strains of streptococci, that is, if we ignore the view of a filtrable virus and believe the disease due to visible organisms only, and second, by following the clinicians too readily in calling the disease "influenza," before the influenza bacillus had been found consistently enough to warrant such a pronouncement.

The clinician has a right to apply the name influenza to the disease, because he has arbitrarily decided on such nomenclature for such symptoms; but the bacteriologist must follow slowly. *Influenza to him* is a specific infection due to the Pfeiffer bacillus. We think the advance in this case has been unjustifiably rapid.

Looking over a group of twenty sputum specimens which were cultivated on blood agar for the purpose of making vaccines, we find that eight showed the presence of Pfeiffer's bacillus, five in almost pure culture and three mixed. These cases were clinically influenza, coryza, bronchitis and asthma. The cultures were made during the winter of 1917-1918. We mention the fact first to show that out here among the natives and the foreigners, infection with the Pfeiffer bacillus is common. However, the point we really want to make is this, that since before the epidemic came the influenza bacillus was a common parasite in respiratory infections, may it not be true that some other organism plays now the rôle of primary infection, while the presence of the influenza bacillus and of the pneumococcus so frequently found is due to the frequency with which these organisms are carried?

The so-called hog cholera bacillus, while found in almost all cases of hog cholera, has no etiologic relationship to the disease, the cause being a filtrable virus.

TRANSMISSION EXPERIMENTS WITH FILTRATES

The experiments here recorded do not lend support to the idea of a filtrable virus. The experiments, although few in number, were carried out on human beings and are therefore of some significance:

Experiment 1.—Blood from two typical cases of influenza was collected in citrate, immediately centrifuged, and the supernatant fluid filtered through a Berkefeld "N" filter. Owing to a lack of enthusiasm among the experimentists the filtrates had to be mixed, and 1 c.c. of each was given to a Korean physician intravenously. The unfiltered bloods were also mixed and a Korean and one of us (F. W. S.) each received 1 c.c. of the pooled blood. The two patients from whom the blood was taken had been sick about twenty-four hours. They were quite prostrated and showed typical symptoms. The temperature of one was 104 and of the other 101. The temperature did not rise higher in either case.

Results.—The experiment, we fear, means little. We were of course all exposed to the infection. The Korean physician who received the filtrate came down with influenza on the third day. He was very sick for almost a week. The senior author, who had taken the unfiltered blood, came down with influenza in forty-eight hours. The attack was slight, although typical. The nasal secretions, which were profuse, gave a pure culture of a diphtheroid bacillus. From the laryngeal secretion an almost pure pneumococcus culture was obtained. The Korean physician suffered from an acute bronchitis for about two weeks, but the influenza bacillus was not isolated. The Korean man who also received the unfiltered blood admitted afterward that he had just recovered from an attack of influenza. Nothing developed in him.

EXPERIMENT 2.—Two students who had not had the disease were each given 2 c.c. of filtered blood from a typical case. The results were negative.

EXPERIMENT 3.—The sputum from another case was taken and thoroughly shaken with saline until a uniform suspension was made. This was not now centrifuged to remove the coarser material, and the supernatant fluid was filtered. Cultures of the filtrate were sterile. Two more healthy students were each given 2 c.c. intravenously.

Results.—Both of the students were made definitely ill within three quarters of an hour after the injection. They reported chills, vomiting, rapid pulse, headache and pains. All symptoms gradually subsided, and within six hours the students had practically recovered. Apparently they suffered from an acute toxemia.

The sputum used in this experiment did not show any influenza bacilli, but gave a mixed growth, the most prevalent colony being a rather large, moist, grayish white, opaque colony. This organism was seen on other plates. It is not *Micrococcus catarrhalis,* although somewhat similar in morphology.

EXPERIMENT 4.—This was similar to the preceding experiment except that the sputum came from a different case. One man only was given 2 c.c. of the sputum filtrate: no results followed.

In all cases the filter used was a Berkefeld "N."

While these experiments are very limited, they would seem to show that the virus, if present in the sputum, is not capable of passing through a Berkefeld "N" filter candle. Also, if present in the blood, the evidence is against its passage through the filter, as only one out of four who received the filtrate developed the disease. With the epidemic raging, and the possibilities of natural infection so numerous, that one among the four men used should succumb to natural infection was most probable cannot be denied. Having passed through the dangers of the epidemic, as well as the fiery trials of the experiments, the subjects considered themselves as very refractory.

SERUM REACTIONS

Complement Fixation Test.—Samples of blood were taken from four patients who had recently recovered (within one week) from acute influenza, and four samples from normal persons. The antigen consisted of a saline suspension of influenza bacilli. After many tests with these bloods it was decided that the antigen was unsatisfactory. A slight increase of antigen caused the negatives to become positive, while in a working strength good positive results could not be obtained with the supposedly positive serums. There did appear to be a slightly greater tendency to fixation of complement on the part of those who had been infected. However, in one instance the blood of a negative patient, that is, of a person who had not had influenza, gave as good fixation of complement as the best positive among the patients' serums.

Agglutination Tests.—Microscopic tests were made on the bloods used in complement fixation. The results were of the same nature; while the patients' serums seemed to agglutinate slightly more than the normal serums, the result was not definite enough to be significant.

Skin Test.—A heavy suspension of influenza bacilli was shaken and extracted in distilled water for two days. The bacteria were then removed by filtration, and the filtrate was used. A class of fifteen students was injected, 0.05 c.c. being given intracutaneously. Within twenty-four hours a definite reaction occurred in all students. There seemed to be no difference between those who had been infected and had recovered and the immunes, or those who were at the time convalescing.

Animal Inoculation.—Four guinea-pigs were inoculated intraperitoneally with the pooled blood and pooled filtrate from two acute cases of influenza, two pigs each receiving 2 c.c. of the pooled Berkefeld filtrate, the remaining two each receiving 2 c.c. of the pooled blood. Night and morning temperatures were taken daily for two weeks; nothing abnormal was recorded.

CONCLUSIONS

Definite conclusions cannot be drawn from such limited work, but the results of our work and those of many others seem to indicate that:

1. The etiology of pandemic influenza remains unknown.
2. Much more evidence is needed to establish the relationship of Pfeiffer's bacillus to the infection.
3. Further experiments with both filtered blood and secretions are necessary in order to determine the possibility for filtrable virus.

Union Medical College.

PULMONARY TUBERCULOSIS AT CAMP CODY, NEW MEXICO

J. F. STUDEBAKER, M.D. (FORT DODGE, IOWA)
Captain, M. C., U. S. Army
CAMP CODY, DEMING, N. M.

The first patient with tuberculosis entered the base hospital, Sept. 14, 1917. Of the cases observed up to Jan. 14, 1919, 114 have been diagnosed tuberculosis, all pulmonary, except one carpal bone, two glandular, two hip and two vertebral. One of the hip patients had active lung findings. No tuberculous respiratory lesion is reported by the examiners in the others of the latter group.

With the exception of four recruits and five civilians, all have had service varying from two days to five years. Seventy-one men served six months or less, and 108 less than one year. The youngest was 18 years of age and the oldest 45; twenty-one were from 18 to 20; eighty-three were in the third decade of life, eight in the fourth and two in the fifth.

These patients belong to the white race except one Filipino and one Indian. Most of them came from Iowa (twenty-three), Nebraska (seventeen), Minnesota (ten), Illinois (seven), Texas (seven), Missouri (six) and Oklahoma (six).

OCCUPATION

In these states, the most actively agricultural of all in America, the highest number came from the rural districts, as the occupation of farming led with thirty-nine. Mechanics numbered eighteen, clerks fourteen, cooks seven, students six, carpenters six, common laborers five, other outdoor vocations ten, and other indoor vocations nine. These figures seem to contradict the belief that sedentary life is more predisposing to the development of tuberculosis than open air pursuits. The reason for this apparent discrepancy is that more men in this camp arrived from the country than from the towns and cities. On the other hand, the figures convince us that tuberculosis is more or less common in those subject to the physical strain, though engaged in the open. Moreover, some indoor occupations prove to be a rest cure for lesions of a few patients, so limited as to produce no untoward symptoms. Similar lesions in those enduring severe labor might be disastrous before a physician is consulted.

FAMILY HISTORY

According to information available, the family history was not really valuable in the study of the cases, for it was negative in eighty-one. In the family history of the other cases, the disease had this incidence: The fathers of eight patients had pulmonary tuberculosis; the mothers of six; the brothers (one each) of three; the sisters (one each) of three; the fathers and mothers of two; the two sisters of one; the father and brother of two; the father, sister and two brothers of one, and the paternal grandparents and father of one.

PREVIOUS PERSONAL HISTORY

The previous personal history, when intelligently given, often reveals the beginning of the tuberculosis, even months or years before the patient suspected anything wrong. The onset in quite a high percentage of cases occurs in some nontuberculous pathologic condition of the respiratory tract which reduces what immunity the patient may have against tuberculosis. Of the series written up in this report, 48 per cent. gave such a previous history. Eighteen per cent. of them had pneumonia; 5 per cent., bronchopneumonia; 10 per cent., measles; 8 per cent., influenza, or so-called la grippe; 2 per cent., bronchitis; 5 per cent., tonsillitis; 6 per cent., pleurisy, and 9 per cent., frequent and protracted colds. Pleurisy and colds lasting six weeks or more were found to be greatly significant.

Of the 114 patients, nineteen had spitting of bloody sputum; two, hemoptysis; thirty-six, chronic cough; eight, blood-free expectoration; forty-four, afternoon rise of temperature; twenty-eight, loss of weight, and twenty-two, night sweats. Four stated that the appetite was extraordinary. Not infrequently toxemia was not apparent, since fever was found absent and digestion undisturbed by a full diet. In two cases of activity, the patients declared that health was always perfect. Thirty-eight gave a negative personal history. One ascribed the cause of tuberculosis to aspiration of a pen point which later was coughed up.

HISTORY OF PRESENT ILLNESS

It is interesting to note the duration of illness as given by tuberculous patients. On inquiry it was found to be from one day to fifteen years. The symptoms of coughing, expectoration, hemoptysis, loss of weight and strength, night sweats, dyspnea, hoarseness, and pain in the chest were relied on in the history of the present illness. Some of the symptoms were more common than others and were usually considered by the patient only slightly if at all deserving attention, namely, chronic cough, tiring easily, afternoon fever (only sixteen reported any fever), and pains in chest.

DIAGNOSIS AND GROSS PATHOLOGY

Pleuritic pains, blood spitting, and sputum associated with frequent persistent colds were valued by the examiner as highly important in the diagnosis. A history of this character, with definite physical findings, made the diagnosis reasonably certain. If, in addition, tubercle bacilli were found in the sputum, the case was considered typical. The findings in about 50 per cent. of the cases in this hospital pointed to a condition of fibrosis, there being present such signs as impaired resonance, increased voice transmission, and abnormal breathing, as bronchial, bronchovesicular, harsh breathing or prolonged expiration. In a few subjects the fibrosis was so extensive that retraction was quite noticeable. In these the breath sounds were more or less suppressed.

This pathologic condition seemed to have its origin most frequently in an upper lobe. If it extended to a lower lobe, the evidence showed great damage done above, with extensive infiltration. The right upper lobe was involved alone in fourteen cases, the left upper lobe in six, both upper lobes in seven, the right upper and lower lobes in four, other right upper groupings in five, other left upper groupings in three, upper bilateral and a lower in three, right lower alone in nineteen, left lower in fifteen, right middle in six, lower bilateral in four, entire right lung in eight, entire left in five, both lungs in four, miliary tuberculosis in four, and no demonstrable focus in two. Because of the tendency of the disease to advance from above downward, this fact was particularly recognized when confusion in the diagnosis arose in the postinfluenzal chest. The showers of constant moist râles in the basal lobe of the lung were not considered significant unless associated with findings of tuberculosis in an upper lobe.

GENERAL OBSERVATIONS

Nearly 50 per cent. of the entire number of patients had an active lesion, for most of them had persistent subcrepitant râles after expiratory cough, some had constant crepitant râles, and a few had both. In two cases, d'Espine's sign was present, three had no physical signs except showers of localized, persistent, moist râles, and two had no evidence whatever except the positive sputum.

In our series here only 5 per cent. had morning rise of temperature, and less than 50 per cent. afternoon fever. The morning pulse was commonly slow, even down to 50. In the afternoon it varied from 64, the lowest, to 130, the highest. It was our observation that, contrary to the teachings of many, the pulse is usually slow in tuberculosis. This was probably due to the almost complete rest cure treatment of those having fever or an acute lesion, exercise being confined to getting about in the ward and on the porches.

DISPOSITION

It was found that seventy-eight had tuberculosis prior to entering federal service. The remaining thirty-six were in the line of duty at the onset of the disease. Forty-four were discharged on a certificate of disability (fifteen one sixth and one one eighth); forty-nine were sent to the Army General Hospital, Fort Bayard, N. M., and three to Army General Hospital Number 21, Denver, for observation and treatment. Nine men were returned to duty. Three soldiers and three civilians died in this hospital within a short time after admission. The other two civilians left the hospital.

LABORATORY WORK

The laboratory work consisted of sputum examinations, blood counts, and the making of roentgenograms (in obscure cases of hilum tuberculosis and extensive fibrosis without definite physical findings). The sputum in twenty-one cases was positive for tubercle bacilli. The method used was repeated daily examinations of morning specimens. The white blood count had a variation of from 3,800 to 19,000. Of striking interest is the fact that not in a single instance were bacilli found in disease of the lower lobes unless associated with pathologic change in an upper lobe, as shown in the accompanying table. Two of the patients had subcrepitant râles only in the right apex, unaccompanied by fever. Four others had absence of afternoon rise of temperature.

SUMMARY

1. In the cases studied, 114 patients had tuberculosis. Seventy-one had served less than six months when first considered unfit for active service.

2. Physical strain may either make an acute process more active or reactivate a healed lesion.

LOBES INVOLVED IN TWENTY-ONE CASES SHOWING POSITIVE SPUTUM

	Number	Temperature	Pulse
Right upper	9	99 to 103.8	70 to 130
Left upper	1	98.2 to 99.2	60 to 80
Both upper	1	98.6	72 to 88
Both upper and right base	1	99.2 to 102.4	84 to 112
Both upper and left lower	3	98.4 to 100.6	72 to 96
Left upper and both lower	1	99 to 102.6	76 to 116
Left upper and hilum	1	98.6	68 to 72
All lobes	2	97 to 98.6	60 to 97
No localization	2	97.4 to 100	72 to 104

3. Family history is of slight value as compared with the previous personal records. Some nontuberculous respiratory disease most commonly appears in the latter.

4. Some patients with active tuberculosis may feel perfectly well, not having any symptoms whatever, no cough, no fever, etc. A severe symptom, as hemoptysis, may be the first warning. A widespread involvement of the lung up to this time may exist without the patient's knowledge.

5. The history of cough, loss of strength and weight, afternoon fever, increased pulse rate and night sweats is of less importance, in the early diagnosis, than that of pleurisy, blood spitting, excessive expectoration, and frequent colds lasting six weeks or longer. Associated with this, the most significant physical finding is that of localized showers of persistent, moist râles after expiratory cough.

6. Pulmonary tuberculosis usually takes a general route from apex or upper lobe downward, and in advanced cases to the opposite side. This should be kept in mind in the differential diagnosis of pulmonary tuberculosis from the influenzal sequelae.

Diet of the Nations at War.—In the diet of nations at war there is a profusion of vegetables, more than in peace time, that contain minerals, roughage and vitamins freely. Go where you will, in the United Kingdom, France, Germany, Switzerland or Holland, one finds the diet of the people today rougher, coarser and containing more vegetables and less concentrated foodstuffs than in peace time.—A. E. Taylor, "War Bread."

LETHARGIC ENCEPHALITIS

PRELIMINARY REPORT

FRANK A. ELY, M.D.
DES MOINES, IOWA

The special article and editorial on "Epidemic or Lethargic Encephalitis,"[1] which recently appeared in The Journal, prompt me to report the following cases:

Case 1.—*History.*—In October, 1918, I was asked to examine a little girl, aged 6 years, suffering from a rather unusual group of symptoms. It seemed that the illness had begun as a mild, febrile disturbance, accompanied by flitting neuralgic pains about the face and other portions of the body. Within forty-eight hours the unusual symptoms developed, which prompted the attending physician to seek counsel. According to his account, the little one had lapsed into a strange state of mental apathy, from which she could hardly be roused; she would not take food, and would not talk voluntarily or answer questions. The bladder and bowels moved involuntarily, and the whole mental picture was one of sluggishness and lethargy. Another unusual feature of the case which attracted his attention was a tendency on the part of the child to maintain almost indefinitely a fixed position when placed in a definite attitude by the examiner, thus resembling very much the catatonic postures of dementia praecox.

Examination.—I found the general demeanor of the patient exactly as related by the physician. There were no neurologic symptoms worthy of mention, with the exception of a possible slight increase in the tendon reflexes of the left upper and lower extremities. The lethargy was very marked. The pupils were equal, regular, and responded promptly to light and distance. There was no apparent involvement of the ocular muscles. The temperature registered 99.4; the pulse, 100. The patient lay in an inert manner with the eyes open, and without moving a muscle. When some playful remark was addressed to her, a very faint suggestion of comprehension was displayed by the muscles of expression. She would not, however, answer questions. I placed her in odd and uncomfortable positions, and she would make no attempt to change to a natural or more comfortable one. This lethargic condition continued for about a week and then gradually cleared up. Within a period of three weeks a complete recovery was made, with the exception of a residuum of slight nervous irritability.

My opportunities for laboratory examinations in this case were almost nil; therefore I am unable to rule out definitely many conditions which must be considered in a case of this kind; but the complete recovery would tend to exclude tuberculous meningitis. The absence of rigidities and all classical evidences of meningitis would serve to disprove its presence, and negative Wassermann tests, obtained since recovery, help to exclude syphilis. On the other hand, the typical lethargic state unaccompanied by any great rise of temperature, together with the fixed postures, corresponds closely to the descriptions given us of lethargic encephalitis.

After examining, in a limited manner, this case, I felt justified in making a diagnosis of encephalitis; but at that time I was unaware of a disease entity of the encephalitic type which features lethargy as being the star symptom in a new syndrome.

Were it not for the fact that I am able to report a thoroughly investigated case which conforms more closely to the symptoms of the disease under consideration, I should have hesitated to make the fragmentary report just given; and my sole object in so doing is to substantiate if possible my belief that this type of illness has been present among us for some time and is not simply a recent development.

[1] Epidemic or Lethargic Encephalitis (Nona), special article, J. A. M. A. 72: 794 (March 15) 1919; Epidemic or Lethargic Encephalitis, editorial, p. 796.

Case 2.—*History.*—Miss M. H. of Radcliffe, Iowa, an unmarried Norwegian woman, aged 18, whose family, previous and menstrual histories were negative, developed a headache and fugacious pains about the face and body, Feb. 10, 1919, which persisted and annoyed her greatly for several days. If there was fever at all, during this time, it was not a prominent symptom. February 19, she consulted her family physician more especially because she could not fully open her eyes, as the result of a double ptosis which was sufficiently marked to prevent the physician from getting a good view of the pupils without holding up the eyelids. A record made at this time indicates that the pupils were equal but narrowly contracted, so much so that it was difficult to determine the reactions to light and distance. The temperature was 99.6, the pulse, 80. A vacant, immobile, expressionless cast of countenance was observed, and a blood count demonstrated only 8,000 leukocytes per cubic millimeter. February 22, it was observed that marked slowing or retardation of all bodily movements had developed. February 24, she became very lethargic, or apathetic, and would take nourishment only when repeatedly and strongly urged. On this date, also, catheterization had to be resorted to, and nystagmoid movements of the eyeballs were noted. February 25, these nystagmoid movements became more marked, being observed when the eyes were directed to either the extreme right or left. During all the time after she came under the observation of her physician, she could walk about, but walked in a very slow, rigid manner. In looking about the act was accomplished by turning the whole body rather than by rotation of the head on the shoulders. As this rigid, lethargic mental and physical attitude increased, it was noticed that she would assume and maintain awkward and unnatural postures, and if her extremities were placed in some strange attitude the posture would be maintained for long periods of time, as in catatonia. Two or more urinalyses, made by her physician before my examination, were entirely negative, and the temperature never exceeded 99.6.

Examination.—February 25, I found the patient to be a robust girl whose facial expression at first disappointed me because I had been led to believe that she was afflicted with a new disease, and I thought I would find, on examination, an ordinary case of dementia praecox. A few moments and some questioning, however, enabled me to determine that the mind, though lethargic, was not that of an insane or demented person. The temperature was 99.4, pulse 80, and respirations 22. The face was expressionless, masked and stolid; the eyes were unwinking; there were occasional nystagmoid jerks to the right or the left, even without being especially elicited. The patient responded to questions with perfect intelligence, after being spoken to repeatedly in a commanding manner. The olfactory sense was normal; the ocular fundi, negative; there was a very slight tendency to bilateral ptosis; the left external rectus was weak; the pupils were oval or irregular, moderately dilated, and responsive to light, distance and consensuality; the conjunctival and palate reflexes were normal; the facial movements were bilaterally and equally restricted, more especially in the movements of expression; the tongue protruded straight; the palate retracted straight; the neck was rigid, but the head was not retracted; marked resistance was noted when the head was passively rotated on the shoulders. Right finger to nose was normal, but the movement was accomplished slowly. Left finger to nose was slow and incoordinate, and was accomplished with a suggestion of coarse tremor involving the whole extremity. The grip of the right hand was normal; of the left hand, diminished. The entire left upper extremity was somewhat paretic. The triceps and supinator jerks were equal and apparently normal, those on the left side being possibly a trifle more brisk. The patellar reflexes were equal but somewhat too brisk. The Achilles reflexes were present and equal, but diminished. The abdominal reflexes were normal. None of the pathologic reflexes, such as the Babinski and Oppenheim phenomena, could be obtained. All types of sensibility appeared to be intact, over all portions of the body. The suggested ataxia of the left upper extremity may possibly have been due to muscular weakness. The heart and lungs were entirely negative, and no abnormalities of the abdominal or pelvic viscera could be detected. Special attention to the liver was given, because of the possibility of the presence of Wilson's disease.

When the patient was placed on her feet and asked to walk across the room, her gait and postures slightly resembled those of Parkinson's disease, with the exception that there was a tendency to stagger, much as one does with cerebellar disease. The head was held with the chin slightly elevated and to the right, with the left ear inclined a little toward the left shoulder. The right upper extremity was slightly abducted from the chest and flexed at the elbow, and the hand carried a little below the level of the groin. When commanded to look around, the patient turned the whole body rather than rotating the head on the shoulders.

Laboratory Investigations.—Blood count revealed: reds, 4,400,000; leukocytes, 7,000; hemoglobin, 80 per cent.; polymorphonuclears, 69 per cent.; lymphocytes, 24 per cent.; large mononuclears, 4.5 per cent.; eosinophils, 1.5 per cent.; transitionals, 2 per cent. Blood cultures were negative. Examination of the spinal fluid gave negative Wassermann tests in all dilutions; the globulin was not increased; there were 12 cells per cubic millimeter; smears were negative; aerobic and anaerobic cultures on glucose serum agar and blood agar were negative.

COMMENT

As this case indicates profound disturbance of the brain and cord, characterized in the beginning by bilateral ptosis, mild febrile reaction, and a state of physical and mental lethargy; and since the laboratory evidence corresponds exactly with that found in epidemic lethargic encephalitis, I feel justified in reporting the case under this diagnostic classification.

There are two or three matters which may be worthy of comment in connection with these reports. In the first place, there was no history of influenza in either of these cases, unless the mild febrile disturbance which ushered in the illness might be so interpreted. Then again, it is of interest to note the similarity that exists between the bodily lethargy in these cases and in Parkinson's disease. When one considers the pathology in both, it is only fair to assume that minute hemorrhagic areas in the corpus striatum, as observed in lethargic encephalitis, may produce the same symptoms as the degenerated areas in the same structures in Parkinson's disease. Another point of interest in connection with Case 2 is the fact that when lumbar puncture was made, and 20 c.c. of spinal fluid were removed, there was a marked improvement in the mental state of the patient, in that she volunteered several statements and asked about some of her jewelry which she had placed in a certain receptacle for safety. This voluntary conversation was the first in which she had indulged for at least five days prior to my examination.

A report just received from the physician in Case 2 is gratifying. The patient is now up and about, and has lost all evidences of mental sluggishness, and the restriction in her movements is hardly noticeable. The most interesting factor in connection with the case is the fact that from the moment the spinal puncture was made she began to make rapid improvement.

Every Typhoid Convalescent a Possible Carrier.—Consider every case that recovers from typhoid as a possible carrier, either continuous or intermittent, temporary or permanent.—*Weekly Bulletin, A. E. F.*

PHYSICAL SIGNS AND THEIR MECHANISM IN ACUTE PULMONARY INFLAMMATION

ROY D. ADAMS, M.D. (Washington, D. C.)
Major, M. C., U. S. Army
AND
CHARLES M. MONTGOMERY, M.D. (Philadelphia)
Captain, M. C., U. S. Army
NEW HAVEN, CONN.

The recent epidemic of acute respiratory inflammation with frequent occurrence of complicating pneumonia has aroused new interest in physical signs associated with the latter condition. This is especially true because of the conspicuous absence of rapid respiration and pulse in the early and moderate degrees of pneumonic involvement and the consequent necessity for careful physical examination. Given the familiar picture of fever, cyanosis, rapid respiration and pulse following an acute bronchial infection, one is reasonably certain of his ground before proceeding farther. Confronted, on the other hand, by a subject who presents moderate fever, who has a respiration rate of 20 to 25, and whose pulse is but moderately accelerated, careful investigation becomes a necessity before one feels assured he is dealing with the usual case of so-called influenza and that a complicating lobular pneumonia has not developed.

No attempt is made in the present paper to encroach on the domain of pathology. Since, however, accuracy of observation has been dependent on postmortem confirmation, some reference to gross pathology and the organs in situ cannot well be omitted. The common picture is that of a lobular pneumonia with tendency toward confluence in the dependent positions. Even in the severer types, however, consolidated patches are usually interspersed with small air-bearing areas. The lobes so involved are in great part firm and their size is increased. An extensive unilateral involvement may displace the heart toward the less involved side, and sometimes pushes the liver downward. Actual bulging of intercostal spaces has been observed in some instances. Especial mention is made of this displacement of organs by the inflamed lung because of the natural tendency to associate such a phenomenon with pleural effusion.

Selecting, for the sake of simplicity, a case from our series that presented a patch roughly 8 cm. in diameter at the left scapular angle, the physical signs recorded are: diminished vocal fremitus; slight percussion dulness; diminished intensity of breath sounds with slightly prolonged expiration; clear, distinct, whispered pectoriloquy; the spoken voice diminished in intensity, the quality altered and pitch raised, as compared with the normal lung; and persistent, localized, fine-bubbling râles.

With confluence of lobular areas eventuating in practically a lobar involvement, vocal fremitus has been found to be frequently diminished; the percussion note impaired, often low-pitched tympany rather than dulness being elicited, breath sounds suppressed or of a weak, bronchovesicular or bronchial character; whispered pectoriloquy clear but not always loud; the spoken voice elevated in pitch, altered in quality, and the intensity exhibiting a wide variation, in some cases being distinctly diminished, in others intensified.

That diminished vocal fremitus and vocal resonance in the presence of dulness and whispered pectoriloquy have been a frequent observation in the absence of any pleural exudate has been confirmed by antemortem roentgenoscopy and roentgenography and by postmortem section. In necropsies early in the epidemic and later during its crest, pleural effusion was exceptional. With the ebbing tide, pleural complications with pus formation have been more frequent. Lack of anything approaching uniformity in physical signs in clear-cut uncomplicated pneumonias has led us to despair of determining the onset of pleural effusion except by the aid of exploratory puncture. In other words, the physical signs of many confluent areas are apt to approach those of ordinary lobar pneumonia, in which the vocal fremitus and resonance are sometimes increased, at others diminished. Variations from the typical picture seem to be accounted for by persisting areas of air-bearing lung and also by the presence of a considerable amount of frothy moisture.

The presence of vocal fremitus and vocal resonance of normal or diminished intensity, in association with bronchial breathing and whispered pectoriloquy such as has frequently occurred in this epidemic (and as is commonly found in other forms of pulmonary consolidation, especially of an acute inflammatory type), is not often referred to in the literature except as combined with fluid in the pleural cavity. Some of the confusion regarding the vocal resonance has resulted from a failure to recognize differences between intensity of sound, on the one hand, and variations in quality and pitch, on the other. When the spoken sounds become less muffled than in health, higher pitched, clearer and closer to the ear, the auscultator must take special care to keep these features entirely distinct from that of simple loudness or intensity, which we believe many fail to do. Austin Flint clearly expressed this distinction, stating that "a concentrated, high-pitched sound, however feeble, is not less a sign of complete or considerable solidification of lung. In other words, intensity is not essential." And again, "increased intensity may cease when bronchophony occurs."

The frequent occurrence of normal or decreased vocal fremitus and resonance plus bronchial breathing and whispered pectoriloquy in cases of consolidation presents a striking contrast to the findings over the normal lung, where the vocal fremitus and resonance are normal in intensity, and bronchial breathing and whispered pectoriloquy are absent. It is plain that sounds of different pitch are not affected similarly in solid and normal lungs, so that any explanation must include one or more factors apart from simple conduction. The factor that we wish here to emphasize as being of great importance in clarifying the subject —one that has been slighted in the literature—is that of the response of the membranous tissue of the normal lung to vibrations included within a certain range of pitch, the result being the production of secondary vibrations, these vibrations being different from those occurring when sounds are transmitted by ordinary conduction, which affects sounds of all pitch alike. This special factor is alluded to by Austin Flint in contrasting the clear-cut sounds heard over a consolidated area with the muffled, humming quality of normal voice sounds, the latter modification being attributed to "secondary vibrations set up in the taut-drawn elastic fibers of the alveolar walls, which blur the distinctness of the original sound waves."

In the comparatively simple case of the solid lung, sounds of varying pitch, after having once escaped from within the bronchial tubes, pass to the surface of the lung and chest wall, with no marked modification except that of diffusion, which acts alike on sounds of different pitch. While sounds of different pitch suffer diminution, they maintain to a great extent their relative degrees of intensity. With the normal lung, on the other hand, sounds of one pitch reach the chest surface well maintained, being even louder than in many cases in which the lung is solid; while sounds of another pitch, lost in the normal lung, become plainly audible in the solid lung.

In the normal lung tissue, then, in contrast to solid lung tissue, sounds of different pitch are affected differently. The lower pitched ones, such as those we can detect by palpation, arrive at the chest surface over a normal lung in a state of considerable intensity, being often more marked than vibrations over solid lung. The higher pitched vibrations, however, such as occur in bronchial breathing and whispered pectoriloquy, are lost under normal conditions. Those that are lost suffer from the natural obstructive features encountered in the normal lung as it exists in the body. These features are, first, the reflective action of the tense membranous tissues of the normal lung, and second, the reflective action of the chest wall as vibrations pass to it from the alveolar air immediately beneath, factors entirely additional to that of diffusion. The lower pitched vibrations, though they may be affected by the obstructive factors just mentioned, are influenced in addition by one or more other factors that are distinctly favorable to their transmission, tending to offset any deintensifying influences. These favorable factors do not modify the higher pitched vibrations of bronchial breathing and whispered pectoriloquy.

The point we wish to emphasize is that the lower pitched vibrations, but not the higher pitched ones, initiate, in our belief, secondary vibrations in the membranous tissues of the normal lung, much as one vibrating tuning fork may cause another tuning fork of proper pitch to vibrate, or as the voice of a patient may set the mattress into readily perceptible vibrations. The principle involved is different from that which is operative in simple conduction. These normal pulmonary membranes are of such tension and structure as to be set into secondary vibration chiefly by vibrations within a limited but rather wide range of pitch.

To repeat, then, these secondary vibrations, excited
by the original relatively low-pitched vibrations com-
ing from the upper respiratory tract, tend, in the nor-
mal lung, to neutralize the obstructive factors just
mentioned, thereby furnishing vibrations plainly per-
ceptible at the chest surface. The higher pitched
vibrations in the normal lung, however, being unas-
sisted by any such favorable factor as that present in
association with secondary vibrations, encounter the
whole force of the obstructive features of the normal
lung unaided, and are therefore lost. The solid lung,
on the other hand, lacks both the special intensifying
and deintensifying factors present in the normal lung.
The solid lung, therefore, having chiefly the factor
of diffusion, which is present also in the normal lung,
to affect the vibrations passing through it, allows the
vibrations to reach the chest wall well preserved, and at the same time exerts an equal effect on vibrations of different pitch. Consequently when a normal lung with its capacity for developing these secondary vibrations is replaced by a solid lung, or a solid lung associated with the fluid in the pleural cavity, the vibrations at the chest surface will show more equal changes than in the case of the normal lung, all the vibrations being relatively increased or decreased.

Regarding fremitus, the hand can feel only vibrations of a relatively low pitch, so that whatever interferes with the normal intensity of these vibrations without substituting some factor equally favorable to their transmission—such a favorable effect being sometimes present, in others absent in disease—will result in a diminution of vocal fremitus.

In explaining the comparative intensities of vibrations over normal and solid lung, we must bear in mind, then, that the normal lung relatively favors the transmission of rather low-pitched vibrations by setting up secondary vibrations, while the solid lung tends to favor the transmission of sounds of all degrees of pitch by offering conditions favorable to simple conduction. It is thus easy to see why a diminished vocal fremitus is sometimes associated with an increase in the vocal resonance, and why voices of equal intensity but different pitch may yield different vibration intensities at the chest surface.

The association of whispered pectoriloquy with normal vocal resonance, frequently encountered over small areas of consolidation, is directly due to the size and location of these areas. Thus any modification of the spoken voice vibrations in these areas is lost to the ear because it is obscured by the vibrations coming from the surrounding normal lung, while the whispered vibrations encounter no such external interference.

EPIDEMICS AFTER WARS *

GEORGE A. SOPER, Ph.D. (New York)
Major, Sanitary Corps, U. S. Army
WASHINGTON, D. C.

The return of two million men from Europe after residing there for several months, to scatter throughout the United States, raises some public health questions of profound interest. Do these men represent any new element of danger to their country in respect to epidemic disease? The final answer to this question must be left to the settlement of time; but the importance of the subject demands that some attention be given it now.

The possibility that the returning troops will bring and spread infection lies largely in the fact that the soldiers have been living abroad in a foreign environment, mixing intimately with associates from various countries and places and in many ways not improbably exposed to infectious diseases.

Against some of the most common of these diseases they have been protected by vaccination, and against others by sanitary safeguards equally appropriate. But experience shows that the barriers raised against disease are not always efficacious. And the belief that pestilential diseases of various sorts have existed in Europe, sometimes very near the fighting lines, that the carrier state is often responsible for epidemics of

---

* From the Division of Infectious Diseases and Laboratories, Office of the Surgeon-General of the Army.

these diseases, and that public sentiment is exerting great pressure in order to have the men demobilized with the greatest practicable haste, adds to the interest with which this subject may be regarded.

There is nothing new in the idea that returning soldiers may bring disease with them. Epidemic diseases have repeatedly been spread by soldiers returning after wars. Smallpox, cholera, typhoid and dysentery are included in the list of diseases for which definite statistics are available. In fact, the instances of troops infecting civil populations are so numerous that it may be said that no modern war has been entirely free from consequences of this kind. A careful statistical study of wars in their relation to epidemics, by Prinzing, was brought out in 1918 by the Carnegie Endowment for International Peace, and it is partly from this valuable source of information that some of the data here given have been taken.

SMALLPOX RESULTING FROM THE FRANCO-PRUSSIAN WAR

The way in which epidemic disease may be spread by soldiers finds illustration in the remarkable pandemic of smallpox which spread through Europe as a result of the Franco-Prussian War. In Germany alone, the disease is estimated to have caused the death of 170,000 persons. It was this outbreak that led to the passage of the law in 1874, making vaccination compulsory in Germany.

Smallpox was conveyed to England probably by French refugees in 1870. The death rate there increased from 0.7 per 10,000 inhabitants in 1869 to 1.2 in 1870, and 10.1 in 1871. It then declined to 8.3 in 1872 and 10 in 1873.

From Germany, smallpox spread into Austria and Bohemia. In Vienna the incidence rose per 10,000 inhabitants from 7.6 in 1871 to 52.7 in 1872; in Prague, from 1.5 in 1870 to 39.7 in 1872.

The smallpox was distributed through Germany and, in fact, brought into that country by French prisoners who came from infected districts. Up to the summer of 1870 there had been practically no smallpox in Germany; but at this time, thousands of French prisoners were, within a short time, brought into the country, and scattered in many directions.

The disease is believed to have been disseminated in various ways, including the following:

1. By prisoners who contracted the disease on their way to Germany.
2. By prisoners from infected localities.
3. By persons in the incubation period of the disease.
4. By carriers.
5. By fomites, that is, by infected clothing, blankets and other effects.

It was believed that nurses, guards and workmen who came into contact with the sick and the well spread the disease. There were thus created many small epidemics which spread until they became great ones. There was eventually formed a pandemic which raged more furiously and extensively than any other fatal epidemic in the course of the nineteenth century.

CHOLERA FOLLOWING THE CRIMEAN WAR

The experiences gained in and after the Crimean War illustrate the danger of cholera which infected troops may exhibit to civilian populations. In the Crimean War the French army carried cholera from Toulon and Marseilles to Gallipoli. At first, only sporadic cases appeared. These occurred wherever the French soldiers went in that vicinity, as Nagra, Varna and Adrianople. During the expedition to Dobrudja, cholera broke out in explosive form, compelling the army to return.

The English soldiers during the seige of Varna were also attacked by cholera. In September, when the scene of war was transferred to the Crimea, cholera broke out violently. The total number of deaths in the French army in the campaign was 12,457, in the English army 4,531, and in the Piedmontese army 1,230. The total combined strength of the troops is believed to have been about 262,000.

Cholera spread far and wide from the scene of the Crimean War, extending through Turkey, around the Black Sea, Greece, Smyrna, the Dardanelles, Constantinople and the Danube principalities. Typhus was also prevalent in the French army in 1855-1856. It was epidemic in the Russian army and in southern Russia. According to Murchison, it was carried by English troops to England, where it was epidemic in various parts of the country in 1856-1857.

TYPHOID, DYSENTERY AND SMALLPOX DUE TO THE AMERICAN CIVIL WAR

In the American Civil War, there was a great deal of typhoid, dysentery and smallpox, and there were serious extensions of these infections among the civil population. Owing to the absence of reliable statistics, it is impossible to state to exactly what extent disease was transmitted to the civil population. The vital statistics of some states, however, afford evidence of an unusual prevalence of disease at this time. For example, in Connecticut, the death rate rose from 1.0 in 1863 to 19.0 in 1864, after which it declined to 16.0 in 1865. In Massachusetts it was 18.5 in 1862, 22.1 in 1863, 22.8 in 1864 and 20.6 in 1865. The Massachusetts statistics show marked increases in typhoid, dysentery and smallpox. It is estimated that over 10,000 people contracted one or more of these diseases during the years of 1863-1865.

TYPHOID AND SMALLPOX AFTER THE SPANISH-AMERICAN WAR

An unmistakable wave of typhoid fever spread over the United States soon after the Spanish-American War. It manifested itself especially in small and in large epidemics. It is believed that the American troops returning from the typhoid-ridden camps carried the infection to their homes. There, sooner or later, in ways characteristic of this disease, the scattered foci gave rise to local outbreaks.

Some of the epidemics were of an explosive and highly sensational character. Included among them was the epidemic at Ithaca in 1903. In this instance there were some 1,300 cases; one in ten of the population was attacked, and about one in a hundred died. In the following year, there was an epidemic of 600 cases at Watertown, N. Y. The epidemic at Butler, Pa., at about the same time, had approximately 2,000 cases. Other epidemics at about this time were Augusta, Me., 1903; Cleveland, 1903-1904; Columbus, Ohio, 1904; Lowell, Mass., 1903; New Haven, Conn., 1901.

The deaths from typhoid fever increased in the cities even when no epidemics occurred. The prevalence so established remained high. Among all the cities of the United States having populations of 100,000, or more, the increase in the number of typhoid cases was as given in the left hand columns of the accompanying table. Still more marked was the increase in cities between 50,000 and 100,000 (right hand columns).

Turning now to the statistics of the commonwealth of Massachusetts, we find that although the death rate from all cases fell from 18.1 in 1897 to 17.5 in 1898, the typhoid rate rose from 2.3 to 2.4, falling decidedly after 1900.

In New York State the typhoid death rate rose from 1.9 in 1897 to 2.6 in 1898. It remained high for several years.

In Michigan the typhoid death rate rose from 1.9 in 1897 to 2.7 in 1898. It remained between 2.4 and 3.8 until after 1909.

PRECAUTIONS AGAINST INFECTION OF CIVIL POPULATIONS

Precautions have been taken on at least two occasions to protect civil populations from infection by troops returning home by water after distant campaigns.

When the French troops were brought back to France, after the Crimean War, only those were allowed to land from the transports who had for some weeks been entirely free from typhus. Several stations for the detention and examination of men were located along the Mediterranean Sea. Here, patients were left behind, while the well, under suitable precautions, were allowed to proceed. Suspected divisions of troops, before disembarking at Marseilles, were quartered at various islands fitted up as detention stations. Here the men were inspected, bathed and reclothed. The disease was not communicated to the civil populations.

INCREASE IN TYPHOID IN CITIES OF THE UNITED STATES

Cities of 100,000 or More		Cities Between 50,000 and 100,000	
Year	Cases	Year	Cases
1897	3,571	1897	747
1898	5,228	1898	923
1899	5,146	1899	1,025
1901	5,168	1900	1,002
1902	5,401	1901	867
1903	6,026	1902	968
1904	5,969	1903	940

After the Russo-Japanese War of 1894-1895, the Japanese employed a twofold system for the elimination of infectious disease among the returning troops. First, infected soldiers and soldiers suspected of being infected were not allowed to join the transports bound for home. Second, quarantine stations were established at Dairei (near Moyi), in Ninoshoma (near Njina) and at Wadano, Misiki (near Kobe).

When the transports reached their destinations, the men were divided into groups of sixty and sent to disinfection establishments, where they were bathed and their effects disinfected. The sick were sent to the hospital, and suspicious cases were quartered in barracks under observation. If infected men had been found on the ship, the ship's crew and officers were treated as suspects. The disinfection stations received 828,376 men for examination. Of this number, 429,762 were disinfected.

These historical and statistical notes show the great danger that returning troops are to civil communities. Sometimes great epidemics have been produced. What is of even more importance, a continuing prevalence of disease over large areas of country for many years has resulted.

Typhoid fever had reached a low point just before our troops returned from the Spanish-American War. The effect of this return was to produce an increase that has continued in many quarters for twenty years. If statistics were available to show the facts, it would be found that a great deal of the smallpox was scattered through the United States as a result of the Spanish-American War. Statistics from the states where most of the smallpox is believed to have occurred are not available.

PRESENT DANGERS AND PRECAUTIONS

Some of the epidemic diseases now to be apprehended from our European troops are of types which, if once well started, might produce great havoc. They include trench fever, typhus, relapsing fever, cholera and plague. Most of these are transmitted by vermin, most commonly, the louse. It is known that conditions do not generally exist in the United States favorable to the transmission of disease by lice, but in certain congested localities and among foreigners this is not the case. Louse infestation is not an unheard of condition in America in peace times. Methods of dealing with the louse problem so as to prevent their extension among troops are practicable, but the extermination of vermin among great civil populations is another matter.

A certain procedure is now being employed to prevent the introduction of louse-borne diseases by our returning troops. All troops are detained at foreign ports for a period of two weeks, during which time they are deloused. Vermin inspections are then made on transports, for occasionally, in spite of rigid instructions, vermin-infested troops slip through. On arriving in this country all troops are sent to debarkation camps, where universal delousing is practiced. Here good facilities are afforded for the detection of vermin and the delousing of the clothing and the bodies of the soldiers.

It is possible that cholera may be brought to the United States by our troops; but so long as political and social conditions remain as they are today, the disease should not gain a footing. Some regiments are probably exposed to it now. For some time cholera has been known to exist in western Russia, Sweden, Spain and Austria-Hungary, and it has recently been reported in Germany and France. It is also at Archangel, or near there.

Cholera has a special meaning for America, not alone because of its previous visitations and the exposure of our troops to it abroad, but also for the reason that conditions are known to exist in some parts of the country which would favor its spread. It will help to understand this matter to remember that the etiology of cholera and typhoid are practically identical. In some parts of the United States typhoid is a very common disease, and there are few places where it does not occur to some extent.

The meaning of this fact is plain and unpleasant to contemplate. The presence of typhoid proves that people are eating one another's excrement. The amount is infinitesimal, but the consequences are large. If cholera was introduced into this country, this fact, and the circumstance that practically nobody is immune to the disease, would favor its spread. It would not occur explosively, of course. Local and unrecognized epidemics would first occur until the disease obtained a footing. If it was not checked then it would do widespread damage.

By some it may be thought that the administrative control of health conditions is so thorough in America that no disease could spread so seriously as to threaten the whole country. This is probably true; but there is no absolute certainty about it. In recent years some infections have spread surprisingly. It is not to be forgotten that infantile paralysis has run a practically unrestricted course through some of our greatest cities; influenza has spread throughout the country; typhoid, like the poor, is always with us, and pneumonia, far from submitting to the efforts of health workers, has assumed great proportions and is on the increase.

Nobody would think it possible that epidemics could gain headway in a country so enlightened as America, where so much attention is paid to personal and domestic hygiene, and where the public welfare is so much the concern of municipal and state governments. The possibility of pestilence in our homes is incredible. And yet it is exactly this attitude of mind that has probably been held wherever epidemics have broken out since the early history of mankind.

The safe attitude of mind to hold in regard to this subject is one of caution. The proper action is preparation. Only persons well trained in public health work should be put in responsible positions where they are to administer and teach the principles of sanitation and of epidemiology. Boards of health should be soundly constituted as to personnel; they should be given sufficient funds to do their work; politics should be rigidly excluded from the administration of the public health. In no department of public affairs is it more important that ability should be the guiding principle in the selection of officers.

The young men returning from Europe have received a certain amount of instruction in personal hygiene and have had opportunities to observe how unremitting is the care that is necessary in order to preserve the health of troops. They have had many useful, and some painful, lessons in this matter. In some cases they will be able to spread the knowledge which they have received. They are capable of arousing considerable interest in public health work. The possibilities in this direction should be utilized. Efforts should be made looking to the prevention of unnecessary sickness and the promotion of health and efficiency on a higher plane than has ever been seen before.

Annual Report of Health Department.—The total estimated population of Hawaii, June 30, 1918, was 256,180. The total number of deaths was 4,010, an increase of 512 over the previous year. The annual rate per thousand of population was 15.65, and excluding the deaths from external causes, 315, the annual rate would be 14.42 from disease alone. In the city of Honolulu there were 1,395 deaths, an increase of 126 over 1916-1917. The total number of births during the year was 9,404, and according to the figures of the Japanese consulate, 5,086 of these were Japanese. The birth rate for the territory was 36.71, as compared with 34.75 for the previous year. There were 2,039 cases of contagious and infectious diseases reported, an increase of 178 over the previous year. The number of cases of typhoid fever reported by the islands was: Oahu, 1,287; Hawaii, 382; Maui, 152; Kauai, 207; Molokai, 11. All sanitary measures were vigorously carried out during the year, including the rat campaign. Tuberculosis reported numbered 937 cases as against 900 for the previous year. June 30, 1918, the number of lepers in the settlement was 608, an increase of twenty-one from the previous year. An advance in treatment was made, apparently, in the employment of four different fatty acid fractions isolated from chaulmoogra oil.

CARDIAC HYPERTROPHY IN PERNICIOUS ANEMIA

NOTE ON NINETEEN NECROPSIES

RICHARD C. CABOT, M.D.
AND
OSCAR RICHARDSON, M.D.
BOSTON

A teamster, American, aged 32, entered the Massachusetts General Hospital, June 14, 1913, with a two years' history and blood typical of pernicious anemia.

In the five years between this date and his death, Sept. 11, 1918, he was seven times in the hospital. Splenectomy was performed in January, 1914; a remission occurred over a year afterward, and five transfusions were performed. He was able to work a considerable part of the time.

HEART HYPERTHOPHY IN PERNICIOUS ANEMIA

Case No.	Number of Necropsy	Diagnosis	Pathologist's Judgment as to the Heart	Heart Wt., Gm.	Remarks
1	2206	Pernicious anemia, puerperal type	Slightly hypertrophied	300	Aged 27; kidneys normal
2	2338	Pernicious anemia	Slightly hypertrophied	310	Slight arteriosclerosis in aortic arch and abdominal aorta; kidneys normal
3	2601	Pernicious anemia	Hypertrophied	436	Slight arteriosclerosis of aorta only; kidneys normal
4	2709	Pernicious anemia	Hypertrophied	358	Slight acute endocarditis of aortic valve; kidneys normal
5	2765	Pernicious anemia	Hypertrophied	450	Arteriosclerosis; kidneys normal; considerable valvular deformity
6	2815	Pernicious anemia	Hypertrophied	285	A very small woman; no other cause for cardiac hypertrophy
7	2925	Pernicious anemia	Hypertrophied	415	Arteries and kidneys nor-normal
8	3010	Pernicious anemia	Slight hypertrophy and dilatation	267	Small emaciated woman; arteries and kidneys normal
9	3060	Pernicious (or aplastic?) anemia	Slight hypertrophy and dilatation	360	Slight subacute glomerulonephritis
10	3084	Pernicious anemia	Hypertrophy and dilatation	363	Arteriosclerosis of abdominal aorta and its branches; slight subacute glomerulonephritis
11	3215	Pernicious anemia	Hypertrophy and dilatation	398	Slight acute glomerulonephritis
12	3374	Pernicious anemia	Hypertrophy and dilatation	472	Slight arteriosclerosis of aorta; arteriosclerosis of coronaries
13	3667	Pernicious anemia	Hypertrophy and dilatation	349	
14	3692	Pernicious anemia	Hypertrophy and dilatation	410	Small band of chronic pericardial adhesions; loose binding; slight acute glomerulonephritis
15	3706	Pernicious anemia	Hypertrophy and dilatation	360	Acute glomerulonephritis (streptococcus sepsis)
16	3806	Pernicious anemia (?)	Dilatation	300	
17	3854	Pernicious anemia	Hypertrophy and dilatation	391	Slight arteriosclerosis
18	3865	Pernicious anemia	Hypertrophy and dilatation	710	
19	3027	Pernicious anemia	No hypertrophy	262	

Scores of blood examinations were made, of which one made in June, 1916, is typical: red cells, 792,000; white cells, 4,000; hemoglobin 20 per cent.

At necropsy there were the usual lesions of pernicious anemia. The marrow showed megaloblastic hyperplasia. The myocardium was fatty, and there was slight edema of the lungs.

The heart weighed 710 gm. The arteries and kidneys were normal and there was nothing in the heart itself or elsewhere to account for hypertrophy.

The results of necropsies in nineteen cases of pernicious anemia at the Massachusetts General Hospital between 1908 and 1919 are given in the accompanying table.

Eighteen out of the nineteen cases that came to necropsy in this ten-year period showed, in the judgment of one of us (O. R.), a definite hypertrophy or dilatation of the heart.

In three of these (Cases 5, 10 and 12), possible causes for the hypertrophy were found in the arteries, the kidneys or valvular lesions of the heart itself. In the other fifteen cases (or 83 per cent.), none of the usual causes (or accompaniments) of cardiac hypertrophy were present.

CONCLUSION

Cardiac hypertrophy, sometimes very considerable, is often associated with pernicious anemia.

DICHLORAMIN-T AND PETROLATUM DRESSING FOR BURNS*

TORALD SOLLMANN, M.D.

CLEVELAND

Dichloramin-T as a wound antiseptic has the very real advantage of furnishing a continuous supply of the antiseptic agent, securing a continuous action over long periods of time, and this with the simplest forms of dressings. A continuous supply of antiseptic is very important in the treatment of infected tissues when it is out of the question to kill all the bacteria at once. The simplest technic is at least an important convenience.

On the other hand, dichloramin-T has some material disadvantages. The solutions must be prepared with some care, and must be fairly fresh, or else tested for the presence of available chlorin. The application causes considerable smarting and burning. This, however, disappears promptly, and can generally be tolerated. On repeated application, it is liable to irritate the skin.

TABLE 1.—TWO PER CENT. DICHLORAMIN-T IN LIQUID SOLVENTS: PERCENTAGE OF THE ADDED DICHLORAMIN-T THAT REMAINS UNDECOMPOSED AT THE TIMES STATED

Solvent	Carbon Tetrachlorid	Chlorcosane	Liquid Petrolatum	Kerosene	Olive Oil
No. of samples tried...	1	2	4	1	1
Period after mixing:					
At once..............	98	100	50 to 100	47	48
1 hour..............	..	86			
1 day..............	97	81 to 94	50 to 78	13	25
3 days..............	..	85 to 96	....	10	17
1 week..............	94	65 to 85	32 to 50	8	8
1 month.........	86	60	33	..	7
Later..............	7 weeks:79	2 mo.:34 4 mo.:16 to 19	2 mo.:29	..	4 mo.:4

These disadvantages are rather minor, in most cases. Certain physical limitations are more serious in connection with burns. The large, open surfaces require protection against mechanical irritation and access of air, and this the dichloramin-T-chlorcosane solution fails to furnish. On the contrary, this solution is absorbed by the dressings, which are then glued by the wound secretions, producing pain and injury when the dressings are changed. Paraffined lace-mesh gauze does not avoid this effectively.

These drawbacks were especially conspicuous in the case of the very painful and slowly healing "mustard gas" (dichlorethylsulphid) burns that came under my observation. When these burns reach the ulcerative stage, they become so sensitive that they have to be protected by thick petrolatum dressings, especially at night. These are undesirable, since they furnish protection to the bacteria as well as to the tissues. Superficial infection therefore flourishes, and the healing must be delayed. It was attempted to compromise the matter, either by alternating the antiseptic and protective dressings or by applying a petrolatum dressing to the wound after it had been painted with dichloramin-T-chlorcosane solution (generally of 2 per cent. strength).

TABLE 2.—TWO PER CENT DICHLORAMIN-T IN PETROLATUM AND IN PARAFFIN OINTMENT: PERCENTAGE OF THE ADDED DICHLORAMIN-T THAT REMAINS UNDECOMPOSED AT THE TIMES STATED

Color of Petrolatum Period after Mixing:	"Superla White"	"Ivory White"	"Onyx"	"Topaz"	"Amber"	"Yellow"	Paraffin Ointment 3:7 (2 Series)
At once.	15	16; 12	10	12	13	20	61-71
1 day....	10	11; 8	5	6	7	13	68
1 week...	7	8; 4	3	6	6	7	50-61
1 month	..	......	..	..	..	5	

It was known, of course, that dichloramin-T is gradually destroyed by ordinary petrolatum; but it was hoped that the destruction would be slow enough so that some of the antiseptic would last from one dressing to the next. Subsequent chemical study of the problem showed that this expectation is not realized, and that the application of ordinary petrolatum over dichloramin-T really amounts merely to alternation of antiseptic and protective treatment.

This prompted a more detailed study of the destruction of dichloramin-T by petrolatum and various solvents. This resulted in the working out of a special petrolatum medium which was found to be sufficiently compatible with dichloramin-T for surgical purposes, so that it may be applied either mixed directly with the dichloramin-T or as a protective dressing over the dichloramin-T.

Attention may be called to the fact that liquid and semiliquid mixtures of petrolatum with active drugs are not subject to the same limitations as is the incorporation of these drugs into solid paraffin. Solid paraffin prevents adequate contact of the mass of the antiseptic with the wound. On the other hand, the layers of liquid and semiliquid mediums in contact with the wounds are continuously changed, so that good contact is secured.

RATE OF DESTRUCTION OF DICHLORAMIN-T IN VARIOUS SOLVENTS

The deterioration was estimated by the changes in the "available chlorin," occurring at successive periods in solutions or mixtures containing originally 2 per cent. of dichloramin-T. I am indebted to Miss J. R. Collacott for these determinations.

Estimation of "Available Chlorin."—This was carried out essentially by the method described in New and Nonofficial Remedies, 1918, p. 158. To duplicate 5 c.c. or 5 gm. samples of the mixtures to be tested, there are added 5 c.c. of glacial acetic acid, 10 c.c. of 10 per cent. potassium iodid, and sufficient carbon tetrachlorid or chloroform to thin the material (usually about 5 c.c.); then a few drops of starch test-solution, and finally, from a buret, sufficient tenth-normal sodium thiosulphate solution to discharge the color.

---

* From the pharmacologic laboratotry of the Western Reserve University School of Medicine.

* This investigation was supported by a grant from the Therapeutic Research Committee of the Council on Pharmacy and Chemistry of the American Medical Association.

Each cubic centimeter of tenth-normal sodium thiosulphate solution corresponds to 0.0177 gm. of available chlorin.

The results are presented in terms of percentage of the amount of available chlorin that should have been liberated, according to the quantity of dichloramin-T originally added.

Three samples of dichloramin-T (Abbott and Squibb), two samples of chlorcosane (Abbott and Squibb) and two samples of liquid petrolatum (Squibb and Stanolind), and five samples of petrolatum (Stanolind) and one of unknown manufacture were used, with practically identical results for each instance.

Liquid Solvents.—The rate of deterioration is shown by Table 1. Carbon tetrachlorid gives the most stable solutions. Chlorcosane solutions keep practically perfect for three days, and are fairly active for a month. Liquid petrolatum solutions show some loss at once, but would preserve a fair efficiency for a month. Kerosene is surprisingly destructive, even more so than olive oil.

Petrolatum.—Commercial petrolatums are highly destructive for dichloramin-T: so much so that the efficiency is at once practically completely destroyed. This is equally true for a series of six samples representing different depth of colors, so that the coloring impurities are not concerned. This is shown in Table 2.

TABLE 3.—TWO PER CENT. DICHLORAMIN-T IN CHLORCOSANE, OVERLAID WITH 20 GM. OF PETROLATUM, ETC.: PERCENTAGE OF THE ADDED DICHLORAMIN-T THAT REMAINS UNDECOMPOSED AT THE TIMES STATED

	Liquid Petrolatum	White Petrolatum (2 Brands)	Yellow Petrolatum	Paraffin Ointment 3:7
At once	100	46-68	98	100
1 hour	95	13-62	42	99
1 day	101	38		
3 days	...	2-7	14	
1 week	87	3	8	60

The last column contrasts this with a "paraffin ointment 3:7" prepared by mixing 30 parts of melted surgical paraffin wax with 70 parts of liquid petrolatum (the Stanolind brands were used). There is considerable deterioration on mixing, but a practical efficiency is maintained for a week.

The physical properties of the paraffin ointment are fairly satisfactory, although it is rather more solid and damp than the commercial petrolatums.

Chlorcosane Solution Overlaid with Petrolatum, Etc.—In order to imitate somewhat the application of a petrolatum dressing over a dichloramin-T dressing, 5 c.c. of chlorcosane containing 2 per cent. of dichloramin-T were placed in bottles with 20 gm. of petrolatum, etc., without mixing. After definite periods, these mixtures were thinned with carbon tetrachlorid or chloroform, and titrated.

The results, reproduced in Table 3, again show the inferiority of petrolatum, which may destroy most of the dichloramin-T in an hour. Both the paraffin ointment 3:7 and the liquid petrolatum were satisfactory.

CONCLUSIONS

An ointment of 3 parts of surgical paraffin and 7 parts of liquid petrolatum has relatively little destructive action on dichloramin-T and can be used as a protective dressing on wounds (burns) treated with dichloramin-T-chlorcosane solution, and even as a basis for a dichloramin-T ointment.

Ordinary petrolatum, irrespective of its color, is very destructive of dichloramin-T, and cannot be used effectively in connection with it.

Liquid petrolatum can be used in emergencies as a vehicle for dichloramin-T, although it is inferior to chlorcosane.

Solutions of dichloramin-T in carbon tetrachlorid are very stable, while those in kerosene or in olive oil deteriorate very rapidly.

Clinical Notes, Suggestions, and New Instruments

A SIMPLE METHOD OF GIVING INTRAVENOUS INFUSIONS

C. S. BLUEMEL, M.A., M.D., DENVER

In giving intravenous infusions in large numbers to dementia praecox patients and morphin addicts, I found it necessary to simplify the usual technic. This simplified technic gets rid of much of the awkward paraphernalia commonly required, and insures cleanliness in giving the infusions.

PREPARATION OF THE SALINE SOLUTION

Nine gm. of U. S. P. sodium chlorid are weighed out and transferred to a small test tube. The salt is shaken down, and the height to which it comes in the tube is marked with a file or label. The test tube then serves as a 9 gm. measure. A number of new quart medicine bottles are washed clean, and 9 gm. of salt are put in each bottle. The bottles are then filled with freshly distilled water to a previously determined and permanently indicated 1,000 c.c. mark. The resultant solution of sodium chlorid is 0.9 per cent. and is of physiologic strength. If a weaker solution is required, or if the bottles do not hold quite 1,000 c.c., the amount of chlorid is, of course, reduced accordingly.[1]

When the solution has been prepared, the bottle is closed with a two-hole rubber stopper. One hole of the stopper carries a piece of glass tubing of sufficient length to reach to the bottom of the bottle. The other hole carries a piece of tubing that projects an inch or more inside the bottle, and extends 2 or 3 inches on the outside. When later the bottle is inverted, the fluid flows out through the shorter tube, while air flows through the longer one to replace it.

When a sufficient number of solutions have been prepared, they are sterilized by boiling for an hour or more in a water-bath. When the solutions have cooled nearly to body temperature, they are ready for intravenous administration. They can, of course, be kept at the required temperature for any length of time by adjusting the flame beneath the water-bath.

ADMINISTRATION OF THE INTRAVENOUS INFUSION

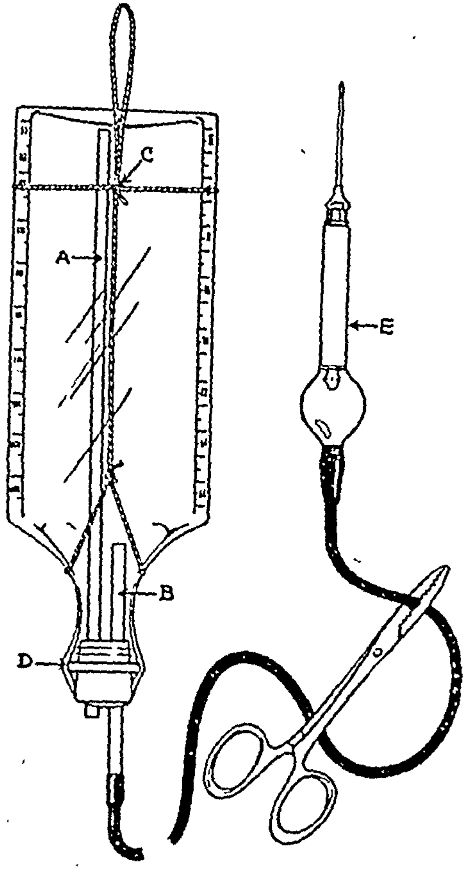
When an intravenous infusion is to be given, a bottle is taken from the water-bath and placed in a sling or holder made of copper wire or string. The sling consists of a loop round the neck of the bottle and a larger loop round the base. Projecting from the larger loop there is a small loop or hook by means of which the bottle is hung in an inverted position from some convenient object. Before the bottle is inverted, the rubber stopper can be made more secure by fastening it with a strip of adhesive tape that has been split for a short distance in the middle so that it can be passed over the glass tubing. The adhesive is then fastened to the top of the stopper and to the sides of the neck of the bottle.

---

[1] The sodium chlorid should be purchased in bottles, not cardboard drums. Salt put up in cardboard containers is usually contaminated with little flakes of foreign matter. The prepared tablets of sodium chlorid can of course be used instead of the granular salt. The objections to them are that they are not readily soluble, and that only the smaller tablets will enter the mouth of the average quart medicine bottle.

To the projecting length of glass tubing there is then attached a piece of sterilized rubber tubing about 6 or 8 feet in length. A glass stem, or "observation tube," carrying a No. 17 or No. 18 Lüer needle is then attached to the other end of the rubber tubing (the observation tube and the needle being, of course, also sterilized). The lumen of the observation tube is expanded at one point to a sphere, and this sphere acts as an air trap by arresting bubbles that come down with the fluid. A hemostat is clamped to the rubber tubing a few inches from the observation tube.

The bottle is hung at any convenient height above the patient within a range of from 2 to 5 feet. The hemostat is released and enough fluid is allowed to flow through the needle to expel the air from the rubber tubing. The hemostat is then clamped again while the patient's arm is being prepared.



Apparatus for giving intravenous infusions *A*, air inlet tube; *B*, outlet tube for solution; *C*, sling for suspending bottle; *D*, adhesive tape securing rubber stopper; *E*, glass observation tube carrying Lüer needle.

A rubber bandage is placed round the patient's upper arm, and the veins are distended by repeated clenching of the fist. A suitable vein is selected, and the site sterilized with alcohol. The needle is then inserted into the vein with a single thrust, and when blood appears in the observation tube, the rubber bandage is removed from the arm and the hemostat is unclamped.

Difficulty in entering the vein is usually due to one or more of three causes: an insufficiently distended vein, a poorly illuminated field of operation, or (most commonly) a blunt needle.

Needles should be sharpened on a smooth stone and examined under a hand lens before they are used. A blunt needle will either push a vein aside or will rip it instead of puncturing it.

When the solution is flowing freely, a "thrill" can be felt by placing a finger on the vein near the point of the needle. The presence of a clear passage into the vein can also be determined at any time by drawing blood from the vein into the observation tube. This is accomplished by pinching off the rubber tubing a few inches from the needle, then momentarily pinching and releasing the short length of tubing that has thus been shut off. As the tubing is released, it aspirates blood into the observation tube. (This pinching process can be readily effected with one hand, the little finger pinching off the tube against the palm of the hand, and the thumb and forefinger performing the aspirating movement.) The flow of the fluid can be further checked by observing the air slowly bubbling into the bottle through the longer length of glass tubing; and also, of course, by observing the gradual descent of the upper level of the fluid. An interruption in the flow of the fluid is usually due to tilting the bevel of the needle against the wall of the vein.

When the bottle has emptied itself, the hemostat is once more clamped on the rubber tubing, the needle is withdrawn, a wad of cotton is pressed at the site of the puncture, and the arm is held elevated for a few minutes.

If desired, several infusions may be given simultaneously. The glass observation tube is raised to the proper angle on a wad of cotton and is held in place with a strip of adhesive tape. One is then free to attend to the next patient.

When the last infusion has been given, the rubber tubing should be placed in a clean glass jar. If the tubing is carefully handled, it will not be necessary to sterilize it with each using, for the inside of the tube cannot readily become contaminated.

When the rubber stopper is removed to refill the bottle, it should not be laid down so that the glass tubing comes in contact with a table top or other contaminated surface. The stopper should be placed in another sterile bottle, which is kept at hand for the purpose. When a number of bottles of solution are being prepared simultaneously, they may be sealed with one-hole rubber stoppers, the hole being lightly plugged with cotton. The double-hole stopper with the glass tubing can then be transferred from bottle to bottle as the infusions are given.

ADVANTAGES

The two great advantages secured by giving intravenous infusions from a medicine bottle in the manner described are cleanliness and simplicity:

Cleanliness.—If the bottles are filled direct from the still, the only possible source of contamination is the salt, and a germ would have to be pretty hardy and weather-beaten to have maintained its existence in contact with salt. The solutions are thus practically sterile before they are sterilized, and after sterilizing they are never exposed to the air or slopped about in gravity tubes or open vessels. Since the outlet tube projects an inch or more into the bottle, it converts the neck of the bottle into a sediment chamber, and thus any foreign particles that may be present gravitate into the neck of the bottle instead of flowing into the outlet tube.

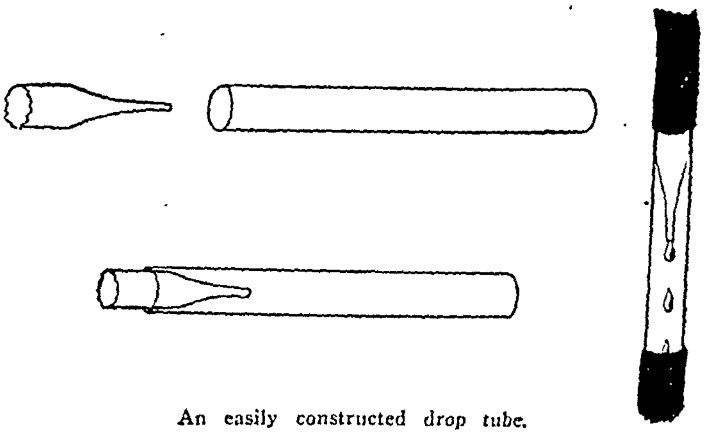
Simplicity.—The solutions are readily prepared, easily carried about, and quickly administered. Using the method described above, one can comfortably give five consecutive infusions in an hour.

900 Metropolitan Building.

A SIMPLE INFUSION DROP TUBE

E. S. Pomeroy, M.D., Winter Quarters, Utah

Finding the usual drop tube for saline infusions very delicate in construction, and the nurse having broken our entire supply of them, we were confronted with the necessity of constructing an apparatus that would indicate the rate of flow for a saline infusion which a serious case demanded immediately.



An easily constructed drop tube.

We found that an ordinary medicine dropper, filed off about an inch above the pointed end, will fit snugly into the end of an ordinary piece of three-eighths inch glass tubing. The rubber tubing is then drawn over them both, leaving the end of the medicine dropper in view within the glass tubing. Greater security is obtained by welding the two together with a flame, but this is not necessary.

TWO CASES OF SKULL FRACTURE WITH SECONDARY MASTOIDITIS AND MENINGITIS, AND IN ONE CASE BRAIN ABSCESS *

J. Morrisset Smith, M.D., New York

I saw these two cases with Dr. William Sharpe at the New York Polyclinic Hospital. Both were cases of skull fracture involving the base, with a secondary mastoiditis and meningitis, and in one case a brain abscess.

REPORT OF CASES

Case 1.—*History*.—A man, aged 43, white, cab driver, with negative family and past history, fell from the seat of a hansom cab, Oct. 31, 1917, and was picked up unconscious, bleeding from both ears.

Physical Examination.—He was well developed and well nourished, and was plethoric. He was still unconscious and bleeding from both ears. The blood was mixed with cerebrospinal fluid. He was in a state of shock, and spinal puncture revealed blood under marked pressure. The reflexes were exaggerated, especially on the left side. The Babinski reflex was present in the left foot. There were no convulsions and no twitchings. Ophthalmoscopic examination revealed marked edematous changes, with blurring of all fundus details and the nasal half and its margins, denoting marked local pressure changes.

First Operation.—November 2, Dr. Sharpe performed a left subtemporal decompression. The usual incision was made and the temporal muscle incised and retracted. The periosteum was separated, revealing a small bluish black area through the lower portion of the bone. The bone was rongeured, exposing the dura under very marked pressure. The dura was incised; a clot appeared through the opening, and bloody cerebrospinal fluid welled out. The clot was subdural; there was no apparent injury to the cortex, excepting that the vessels were markedly congested. The clot was removed and the wound closed as usual with two drains. The patient left the table in good condition. From the time of admission, except for occasional twitchings about the neck, shoulders and arms, unconsciousness was marked. The patient moved the arms, and turned to either side. Operation was decided on because of the prolonged unconsciousness, blood in the cerebrospinal fluid, and changes in the fundus oculi. The temperature was 102, pulse 94 and respiration 18. The patient regained consciousness at 2:30 p. m. (four hours after the operation).

Second Operation.—Sixteen days later I examined the patient and found a tender postauricular swelling under the right ear, a profuse discharge from the canal, the neck partially rigid, and Kernig's sign present. The patient was stuporous but could be momentarily aroused. The spinal fluid was cloudy. No bacteria were revealed on culture of fluid. The temperature ranged from 99.5 to 101. A diagnosis of mastoiditis and meningitis was made and a mastoid operation performed. Exposure of the mastoid cortex revealed a fracture running below the temporal ridge forward to the spine of Henle. The entire mastoid cavity was necrotic and filled with pus. The fracture extended down into the angle between the cerebral and the cerebellar dura. The mastoid cells were thoroughly exenterated, and the usual closure and dressing made. The patient died two days later of meningitis.

Case 2.—*History*.—A woman, aged 40, white, with negative family and past history, was injured in an automobile accident, Oct. 31, 1917, and bled from the right ear. She was admitted to the Polyclinic Hospital one week later.

Examination.—The patient was well developed and well nourished. There were ecchymoses of both eyes and the mastoid regions. There was a scalp wound 3 inches long in the occipital region. There were multiple contusions with ecchymoses in the neck, trunk and extremities. The knee jerk was increased. The abdominal reflexes were absent. There was no Babinski reflex. Lumbar puncture revealed the fluid bloody and under high pressure. The pupils were slightly enlarged, the left being the larger of the two. On admission the temperature was 101.6 and the pulse 84. In the right eye there were mild edematous changes of the upper nasal quadrant; in the left eye, no changes.

A second lumbar puncture disclosed cloudy spinal fluid with symptoms of meningitis.

I saw this patient about three weeks after admission, and my examination revealed almost the identical condition as in Case 1, an unquestionable mastoiditis with marked postauricular tenderness, slight edema, profuse discharge from the canal, haziness of the mental condition, a positive Kernig's sign, the neck stiff, and cloudy spinal fluid, with a report of no bacteria.

Operation was deferred at this time, and the patient was observed for two weeks. The general condition remained about the same. Another lumbar puncture was done, and the patient showed a slight improvement with the mastoiditis more marked.

Operation.—At this point I decided to drain the mastoid. Instead of performing a complete mastoid operation as in the first case I very quickly exposed the cortex, and there was a fracture running forward to the spine of Henle just under the temporal ridge. I then removed the cortex, avoiding the hammer and chisel, and stopped.

The patient immediately began to improve and steadily gained both physically and mentally, until she was finally taken home, abount two months later, with the mastoid completely healed.

She showed continuous improvement until Feb. 18, 1918, while in the neurologic clinic to see Dr. Sharpe, when she developed epileptic seizures beginning in the face, right arm and leg, and then general convulsions lasting half a minute. She was admitted to the ward for observation. There were no seizures in three days, and she again went home.

March 8, she was again admitted, showing right facial paralysis with impaired sensation; motor and sensory aphasia; weakness with increased reflexes in the right arm; headache, and tenderness over the left frontoparietal region. The pulse and temperature were normal. The patient was weak and lethargic. Consciousness was not impaired.

Second Operation.—March 18, Dr. Sharpe performed a left subtemporal decompression and drainage. The usual incision was made. The dura was thick and not transparent, the fluid was not under tension, and very little cerebrospinal fluid exuded. The dura was adherent to the cortex, which was grayish and showed signs of previous meningitis. The cortex did not pulsate.

The left frontoparietal region was explored with a hollow needle. A large abscess cavity was found about 4 cm. from the surface of the cortex. A large amount of thick, grayish pus was evacuated which showed pure culture of streptococcus. The usual closure was made with drainage. The patient finally died of meningitis three weeks later.

COMMENT

Was there a true meningitis in these cases, presenting all the clinical symptoms plus a cloudy spinal fluid but no bacteria? Owing to the fact that some patients recover, opinions differ as to the presence of real meningitis.

I think that a bacterial meningitis is present but that the infection becomes localized or walled off, as in these cases, and that this accounts for the absence of free bacteria in the fluid as well as recovery in some of the cases, remembering that in a diffuse meningitis they die without fail.

The two patients showed some improvement following lumbar puncture. While repeated lumbar punctures have been of no avail in cases of diffuse meningitis, it is worth trying as a therapeutic measure when there is evidence of localization.

The prognosis at best in cases of this type is very poor, and the decision as to the best thing to do for the patient is a difficult one. Should I again be confronted by a similar situation I would follow the method used in Case 2, since we establish drainage by simply removing the cortex and do not interfere with the protecting wall which nature may have thrown around the line of fracture.

45 East Sixty-Second Street.

---

* Reported before the New York Academy of Medicine, March 13, 1919.

SUPERIORITY OF THE METHOD OF ICE-BOX FIXATION IN THE WASSERMANN TEST *

Oscar Berghausen, B.A., M.D., Cincinnati

In 1917, Smith and MacNeal reported results obtained in a comparative study of different antigens and of different temperatures of incubation in the Wassermann test. Last summer the method of ice-box fixation was employed at the Cincinnati General Hospital with such gratifying results that it is now employed as a routine. Previously the classical test in which three different antigens were used, a double unit of complement and amboceptor, in a final volume of 2.5 c.c., with incubation at 37 C. in a water bath, was employed. Comparative studies have convinced us that when small amounts of antigen are used with fixation at the low temperatures of 0 and 2 C., false positive reactions are avoided and reliable results are obtained.

PREPARATION OF ANTIGENS AND THE TECHNIC OF THE TEST

The cholesterinized antigen was prepared by treating 100 gm. of beef heart with 900 c.c. of alcohol in the usual way and adding 0.4 gm. of cholesterin to 100 c.c. of the extract. A dilution of 1:20 in physiologic sodium chlorid solution was used in the test, and its hemolytic, anticomplementary and antigenic properties were determined. The regular alcoholic extract antigen was prepared from a syphilitic heart, and a dilution of 1:10 was used in the test. The Noguchi acetone insoluble fraction was prepared from a beef heart extract, and a dilution of 1:20 was used in the test. The antigenic values were determined in the usual manner, except that over night fixation in the refrigerator was employed. This usually meant a fixation at 0 C., or slightly above this point, for a period of from eighteen to twenty hours. To avoid freezing, the racks were covered with a sterile towel. The next morning the racks were placed at room temperature to warm; then the suspension of sheep corpuscles (5 per cent.) was added, and the racks placed in a water bath at 37 C. for from ten to fifteen minutes. They were then removed and preliminary readings made. When hemolysis was complete in all the tubes of a single test, the reaction was reported as negative. Special studies to determine whether such serums contained sufficient natural amboceptor to dissolve an additional 0.2 c.c. of corpuscles disclosed that such a procedure was not advisable as a routine. When partial hemolysis occurred in all the tubes of a single test, a single unit of amboceptor was found sufficient. When no hemolysis occurred, a double unit of amboceptor was added. When the control tube was completely hemolyzed and the tubes containing the antigen were partially or completely inhibited, a single or double unit of amboceptor was added. Final readings were made after an incubation of from thirty to sixty minutes in the water bath at 37 C. The complement was prepared in the usual way by diluting guinea-pig serum 1:10 with salt water. A double unit of complement was employed. The unit of amboceptor was usually 0.1 c.c. of 1:1,000 immune rabbit serum. We aimed to have a final dilution of 2.5 c.c. when amboceptor was added. Such single tests as needed no additional amount of amboceptor had a final volume of slightly less than 2.5 c.c. Small amounts of antigen were usually employed, from 0.2 to 0.3 c.c., four to five times this amount still giving complete hemolysis with a normal serum and ice-box fixation. We apparently were dealing with a cholesterinized antigen which in these small amounts did not yield the false positive results so frequently described. Only 0.1 c.c. of serum was employed in the control tube, to determine the presence or absence of sufficient amount of natural antisheep amboceptor. When the serum is anticomplementary, this property is detected very easily. At present we are using a similar technic in the examination of spinal fluids, employing 0.5 c.c. for the test.

RESULTS OF THE TESTS

Although we have examined about 2,000 serums with the technic described above, we shall discuss in detail only the results obtained in the examination of 220 serums, since we had better opportunities for comparison.

In Table 1 it is shown that ice-box fixation gives 6 per cent. more positive reactions in known syphilitic cases, as compared to fixation in the water bath at 37 C. for one hour. In the latter method, 0.2 c.c. of serum was used in each tube; in the former, 0.1 c.c. This method was employed to determine whether or not inactivation of the serums tended to produce more negative reactions. Although twice the amount of serum was used in 2.5 c.c. volume in the water bath fixation method, the results were still inferior to those obtained with ice-box fixation.

TABLE 1.—SUMMARIZED RESULTS OF ONE HUNDRED AND FORTY-TWO TESTS ON SYPHILITIC PATIENTS

Fixation	Positive		Negative	
	Number	Per Cent.	Number	Per Cent.
Water bath	91	64	51	36
Ice-box	100	70	42	30

In Table 2 it will be seen that the serum of seventy-eight patients definitely not syphilitic gave negative reactions, the technic being the same as that described under Table 1.

TABLE 2.—SUMMARIZED RESULTS OF SEVENTY-EIGHT TESTS ON PATIENTS NOT SYPHILITIC

Fixation	Positive		Negative	
	Number	Per Cent.	Number	Per Cent.
Water bath	0	0	78	100
Ice-box	0	0	78	100

In Table 3 are given the results obtained by examining both active and inactive serum. The Hecht-Gradwohl modification was employed; in eight serums the hemolytic index was too low. The technic of the Wassermann tests was the same as described under Table 1, inactive serum being used.

TABLE 3.—COMPARATIVE RESULTS OF WASSERMANN AND HECHT TESTS ON ONE HUNDRED AND TEN SERUMS

Method	Positive		Negative	
	Number	Per Cent.	Number	Per Cent.
Wassermann water bath fixation	37	33.6	73	66.4
Wassermann ice-box fixation	49	44.5	61	55.5
Hecht	35	34.3	67	65.7

In Table 4, comparative results with different antigens and ice-box fixation over varying lengths of time are tabulated. Ice-box fixation increases the number of positive reactions when alcoholic extracts are used, that is, such fixation enhances the value of the simple alcoholic extract. Smith and MacNeal[1] found a greater number of positive reactions with cholesterinized antigen. Possibly our results are due to the particular antigens used.

TABLE 4.—COMPARATIVE RESULTS WITH DIFFERENT ANTIGENS AND ICE-BOX FIXATION OVER VARYING LENGTHS OF TIME

Antigen	4 Hrs. Ice-Box Fixation			Over Night Ice-Box Fixation		
	Positive	Negative	Total	Positive	Negative	Total
Alcoholic	35	62	87	35	52	87
Cholesterinized	21	66	87	33	54	87

CONCLUSIONS

1. Ice-box fixation, from eighteen to twenty hours at 0 and 2 C., increases the number of positive reactions with serum of known syphilitic patients.
2. We have no evidence to show that it tends to cause false positive reactions.
3. In the examination of a large number of serums, ice-box fixation, simple alcoholic extract of a syphilitic organ being used as antigen, yields satisfactory results.

19 West Seventh Street.

TYPHOID IN THE LARGE CITIES OF THE UNITED STATES IN 1918

SEVENTH ANNUAL REPORT

THE JOURNAL presents its seventh annual survey[1] of typhoid fever mortality in cities of the United States having more than 100,000 population. The cities included in the summary number sixty, and are the same as those reported on last year.[2]

TABLE 1.—DEATH RATES FROM TYPHOID IN CITIES OF GROUP 1 (MORE THAN 500,000 POPULATION) *

	Deaths from Typhoid per 100,000 Population				
	1918	1917	1916	Average 1911-1915	Average 1906-1910
Chicago	1.4	1.7	5.2	8.2	15.8
Boston	2.5	2.9	3.5	8.0	16.0
Philadelphia	3.0	6.2	7.8	11.2	41.7
New York	3.7	4.0	3.8	8.0	13.5
Cleveland	4.7	7.1	5.3	10.0	15.7
St. Louis	7.2	7.5	9.4	12.1	14.7
Pittsburgh	9.8	11.2	8.6	15.9	65.0
Detroit	10 0	17.8	15.0	18.1	21.1
Baltimore	12.2	15.5	18.0	23.7	35.1

* The population estimates of the U. S. Census Bureau have been used in calculating the rates in this and the following tables. It should be noted, however, that the length of time since the 1910 census makes all population estimates more or less uncertain. The Census Bureau does not make any estimate of the population of Denver, Portland, Ore., Seattle and Spokane. The population of Washington, D. C., is estimated by an alternative method.

The nine large cities in Group 1, comprising about 15 per cent. of the total population of the country, show again a very notable improvement in their typhoid record. Chicago, Boston, Philadelphia, New York, Cleveland, Detroit and Baltimore, in fact, record the lowest typhoid rates yet reached in their sanitary history. A particularly encouraging item in this group is the marked reduction in Detroit, a city that for several years has had an excessive amount of typhoid for a Northern city.

Baltimore also shows marked improvement. Although this city is handicapped by its negro population and by other circumstances shared by most Southern cities, its improvement as respects typhoid is little short of marvelous. Its rate in 1918 was lower than the average 1906-1910 rate for any member of Group 1, and about one-third its own rate for that period. Undoubtedly the purification of the water supply has had much to do with typhoid diminution; but the steady and energetic efforts of the health department in other ways have undoubtedly had great influence. Baltimore probably suffers disproportionately from imported typhoid, since the neighboring rural districts seem to be rather heavily infected.

The city of New York issues the most complete and satisfactory statements regarding typhoid of any of this group. At the end of each quarter of the year a report is made in the *Weekly Bulletin* regarding the results of blood samples sent to the laboratory, of modes of infection as determined by investigation of individual cases, of immunization, etc. These reports are of great value both for determination of actual channels of infection and as furnishing a basis for frequent comparison. The report, for example, of typhoid for the third quarter of the year shows that thirty-seven cases were traced to contact with active cases of typhoid, and that there was a total of eighty-three contact cases and twenty-three due to milk contamination. One hundred and thirty-five cases were considered to be out-of-town infections. Considering the difficulty of tracing chronic carrier and other contact cases, these figures would seem to indicate that a very large proportion of the typhoid in New York City is due to contact and to milk contamination. An interesting outbreak of typhoid in an institution is described in one of the July numbers of the *Weekly Bulletin*. The New York reports furnish a model for other cities. It is doubtful, indeed, if there is any other large city in the world in which typhoid studies are so systematically conceived and so efficiently carried out. The effect is seen in the remarkable diminution in typhoid in New York City. The department wisely urges the more extensive practice of typhoid immunization as a means for further reducing typhoid prevalence. The following significant paragraph appears in an issue of the *Weekly Bulletin:*

> While it is the practice in most hospitals in this city to immunize student nurses, it is interesting to record that recently the failure of one institution to carry out this procedure resulted in the death of a nurse who had been caring for a typhoid fever patient. This death, like most other typhoid fever deaths, was entirely preventable, and it is to be blamed on those who did not enforce this proved measure of protection, since nurses are necessarily very much exposed.

Too great publicity cannot be given to the responsibility of hospital authorities for imposing typhoid immunization. Are other health departments doing as much as New York?

TABLE 2.—DEATH RATES FROM TYPHOID IN CITIES OF GROUP 2 (FROM 300,000 TO 500,000 POPULATION)

	Deaths from Typhoid per 100,000 Population				
	1918	1917	1916	Average 1911-1915	Average 1906-1910
Seattle	2.3	5.1	3.0	5.7	25.2
Los Angeles	2.8	5.2	3.1	10.7	19.0
Newark, N. J.	3.5	3.5	5.3	6.8	14.6
Cincinnati	4.1	4.1	3.4	7.8	30.1
San Francisco	4.6	4.9	3.4	13.6	27.3
Milwaukee	6.2	5.9	14.9	13.6	27.0
Minneapolis	7.6	5.9	5.8	10.6	32.1
Buffalo	7.8	10.1	10.9	15.4	22.8
Washington	11.9	13.2	12.6	17.2	36.7
New Orleans	20.1	23.0	23.4	20.9	35.6

Most of the cities in Group 2 (from 300,000 to 500,000 population) show improvement over the 1917 rates, the changes in Seattle and Los Angeles being especially noticeable. Every city in the group with one exception seems likely to have a lower record for the present five-year period than for the quinquennium

---

[1] The preceding articles were published May 31, 1913, p. 1702; May 9, 1914, p. 1473; April 17, 1915, p. 1322; April 22, 1916, p. 1305; March 17, 1917, p. 845, and March 16, 1918, p. 777.

[2] The number of typhoid deaths has been sent us by the local officer of health, and the rates have been calculated on the basis of population estimates made according to the method of the U. S. Census Bureau (see, however, the note to Table 1). It may perhaps be noted that the figures kindly furnished us by the municipal officials include the deaths of nonresidents as well as residents occurring within the city limits. In some instances this undoubtedly gives an exaggerated impression of the amount of typhoid fever in a community, but at present statisticians are agreed that "the attempt to eliminate the deaths of nonresidents would often result in an understatement of the true mortality" (Bureau of the Census, Mortality Statistics, 1912, p. 13). It is probably true that in 1918 a number of cities suffered disproportionately from the importation of nonresident cases of typhoid. This is particularly the case with some cities that have had a mushroom growth of war industries in their immediate vicinity. It does not seem possible, however, to make any fair adjustment by deducting all nonresident deaths, especially since the general shifting of population has been unusually great and very uneven.

1911-1915. The exception is New Orleans, which remains in a rather mediocre position and has bettered its typhoid rate but little, if any, during the last ten years.

Milwaukee again makes a most excellent showing. This city remains a fine example of the success that may be reached in treating a badly polluted water by the chlorination process. The use of chlorin under the conditions existing in Milwaukee has its difficult administrative side, and it is greatly to the credit of the city authorities that they continue to exercise unceasing vigilance. Complaints of the odor of the water in Milwaukee seem to be rather frequent, but the health commissioner does not allow these to swerve him from his course. The statement is frankly made that while chlorin in the water is disagreeable and even obnoxious, it is necessary and is not poisonous. The occasional occurrence of unpleasant odors is certainly a small price to pay for the relatively high degree of security from water-borne infection that Milwaukee enjoys. It should be noted also that in Milwaukee, as in other cities, by no means all the odors in the water are to be charged up against the chlorination process. The refuse from manufacturing industries must take its share.

TABLE 3.—DEATH RATES FROM TYPHOID IN CITIES OF GROUP 3 (FROM 200,000 TO 300,000 POPULATION)

	Deaths from Typhoid per 100,000 Population				
	1918	1917	1916	Average 1911-1915	Average 1906-1910
Rochester, N. Y.	1.9	3.1	5.1	9.6	12.8
St. Paul.............	3.5	2.4	4.9	9.2	18.3
Jersey City..........	4.1	3.2	6.8	7.2	12.6
Providence, R. I.	4.5	5.4	5.1	10.2	14.3
Portland, Ore.	5.6	5.5	4.6	10.8	23.2
Indianapolis.........	6.6	10.0	26.6	20.5	30.4
Denver...............	8.7	5.1	7.2	12.0	37.5
Columbus, Ohio.....	8.9	7.6	13.4	15.8	40.0
Louisville, Ky.	12.4	12.2	9.7	19.7	52.7
Kansas City, Mo. ...	13.7	10.0	10.6	16.2	35.6

Typhoid in Washington has remained at about the same level for several years. Washington, like Baltimore, probably suffers more than some cities from being surrounded by a zone of communities that contribute infection to the city population. An outbreak in Alexandria, Va., is thought to have helped to swell the list of typhoid cases in Washington during the past year.

Minneapolis has a somewhat higher rate than in 1917 and 1916. Raw milk is thought to have caused some cases in Minneapolis at the beginning of 1918.

Group 3 (from 200,000 to 300,000 population), which last year made an exceptionally good record, now shows an increase in the typhoid rate in seven out of ten cities. Except in Kansas City and Denver, however, the increases are not very great. Four of the cities report rates under 5, as against 3 in the 1917 table.

Indianapolis, which prior to 1917 had a high typhoid rate, now seems well established in the same rank with other Northern cities. The population estimate of Denver is quite uncertain. The Census Bureau [illegible] no estimate for the population of that city, [illegible] the same thing is true of Portland, Ore. Louis[illegible] comes off especially well this year, considering [illegible] war conditions that have prevailed in the neigh[illegible] that city. The typhoid increase in Kansas [illegible] to be attributable to an accident to the water chlorination plant in July. Apparently raw river water entered the distributing mains at that time, and the bacterial examinations showed the presence of *B. coli*.

The cities of Group 4 make, on the whole, a better showing than in 1917. New Haven more than maintains its excellent showing of the past two years. Fall River cuts its 1917 rate in half. Paterson, which last year suffered from peculiar local conditions, again resumes its place as one of the leaders of this group. Toledo for the second successive year has a typhoid rate under 10. It seems evident that the conditions in Toledo which gave that city unenviable notoriety for some years before 1917 have been largely remedied. The Ohio State Board of Health seems to be keeping close watch on the Toledo water supply.

TABLE 4.—DEATH RATES FROM TYPHOID IN CITIES OF GROUP 4 (FROM 125,000 TO 200,000 POPULATION)

	Deaths from Typhoid per 100,000 Population				
	1918	1917	1916	Average 1911-1915	Average 1906-1910
Paterson, N. J.	2.1	11.3	1.4	9.1	19.3
Worcester, Mass.	4.6	4.8	3.7	5.0	11.8
Oakland, Calif.	4.7	1.9	4.0	8.7	21.5
Omaha...............	5.0	6.4	5.1	14.9	40.7
New Haven, Conn. ..	5.2	9.2	8.0	18.2	30.8
Scranton, Pa.	5.2	6.0	5.4	9.3	31.5
Fall River, Mass.	7.0	16.9	10.9	13.4	13.5
Spokane, Wash.	9.1	7.1	2.0	17.1	50.3
Syracuse, N. Y.	9.3	6.3	12.2	12.3	15.6
Toledo, Ohio.........	9.9	9.7	22.9	31.4	37.5
Atlanta, Ga.	14.4	16.8	17.9	31.4	58.4
Memphis, Tenn.	14.9	21.1	36.3	42.5	35.3
Birmingham, Ala. ...	31.9	54.1	42.6	....	....
Richmond, Va.	65.3	7.0	24.1	15.7	34.0

Atlanta and Memphis again make good records for Southern cities. The campaign against typhoid by the Memphis health department is certainly having its effect. Atlanta seems to have had trouble with its water supply from running its filters at too high a rate, leading at one time to deterioration in the bacterial quality of the filtered water. A chlorinating plant was installed, however, and such danger as existed from a contaminated water supply does not seem to have been greatly prolonged. It is a question, indeed, how much, if any, typhoid was caused from overburdening the filters. The lower typhoid death rate in Atlanta does not indicate that very much trouble actually occurred from this source. Birmingham still has twice as much typhoid as Atlanta and Memphis.

TABLE 5.—DEATH RATES FROM TYPHOID IN CITIES OF GROUP 5 (FROM 100,000 TO 125,000 POPULATION)

	Deaths from Typhoid per 100,000 Population				
	1918	1917	1916	Average 1911-1915	Average 1906-1910

* From the Pa

Richmond has a sad lapse. We are not aware that any report on the high typhoid fever in Richmond in 1918 has been published. A rate of 65, however, should not be allowed to pass without a searching inquiry into causes and remedy.

Group 5 (from 100,000 to 125,000 population) shows a marked relative improvement over 1917. Dayton, which for some years has had a high rate for a Northern city, gives evidence of changing conditions. The improvement in that city is attributed by the local authorities to careful supervision of the private water supplies in and about the city. Many private wells and springs are said to have been condemned on account of their contaminated condition. Dallas, a city that has the advantage of employing an expert director of sanitation, has reduced its typhoid rate materially and ranks as one of the very best of Southern cities. With the present rate of improvement, Dallas may soon serve as a model for other communities. There is no doubt that, simply as an advertisement, expert health supervision will repay any community. Grand Rapids continues the steady improvement of the past few years, and seems finally to be getting the good results from the operation of its filtration plant that were expected earlier.

TABLE 6.—DEATH RATES FROM TYPHOID IN 1918

First Rank (Under 5.0)			
Chicago	1.4	Springfield, Mass.	3.6
Lowell, Mass.	1.8	Camden, N. J.	3.6
Rochester, N. Y.	1.9	New York	3.7
Paterson, N. J.	2.1	Bridgeport, Conn.	3.9
Seattle	2.3	Cincinnati	4.1
Boston	2.5	Jersey City	4.1
Cambridge, Mass.	2.7	Providence, R. I.	4.5
Los Angeles	2.8	San Francisco	1.6
Philadelphia	3.0	Worcester, Mass.	4.6
Newark, N. J.	3.5	Oakland, Calif.	4.7
St. Paul	3.5	Cleveland	4.7
Second Rank (from 5.0 to 10.0)			
Omaha	5.0	St. Louis	7.2
New Haven, Conn.	5.2	Minneapolis	7.6
Scranton, Pa.	5.2	Buffalo	7.8
Portland, Ore.	5.6	New Bedford, Mass.	8.0
Tacoma, Wash.	5.7	Denver	8.7
Milwaukee	6.2	Columbus, Ohio	8.9
Indianapolis	6.6	Spokane, Wash.	9.1
Dayton, Ohio	6.9	Syracuse, N. Y.	9.3
Hartford, Conn.	7.0	Trenton, N. J.	9.4
Fall River, Mass.	7.0	Pittsburgh	9.8
Salt Lake City	7.1	Toledo, Ohio	9.9
Third Rank (from 10.0 to 20.0)			
Detroit	10.0	Louisville, Ky.	12.4
Grand Rapids, Mich.	10.3	Dallas, Texas	12.6
Albany, N. Y.	10.7	Kansas City, Mo.	13.7
Washington, D. C.	11.9	Atlanta, Ga.	14.4
Baltimore	12.2	Memphis, Tenn.	14.9
Reading, Pa.	12.3		
Fourth Rank (Over 20.0)			
New Orleans	20.1	San Antonio, Texas	54.3
Birmingham, Ala.	31.9	Richmond, Va.	65.3
Nashville, Tenn.	32.7		

Two cities in the group, Nashville and San Antonio, have experienced considerable typhoid increases, although the 1916-1918 average in Nashville is considerably below that of earlier years. There is reason to believe that the actual population in Nashville was considerably higher than the estimated population; and there seems no doubt that the Nashville typhoid rate was unduly swollen by cases brought in from war industry plants in the vicinity. San Antonio reaches the high figure of 54.3, more than double the preceding year. What was the matter? Will the chamber of commerce of that town advertise the typhoid rate in Northern papers, when presenting the claims of San Antonio as a winter resort? Aside from the two cities last named, the group as a whole compares favorably with the groups of cities with larger population.

In 1918, forty cities had a lower typhoid rate than in 1917; twenty, a higher. Forty-four cities had a typhoid rate under 10, as compared with thirty-seven in 1917, thirty-five in 1916 and thirty-two in 1915. In twenty-two cities the death rate from typhoid fever was under 5.0 during 1918; this was true of only fourteen cities in 1917.

TABLE 7.—AVERAGE DEATHS FROM TYPHOID PER HUNDRED THOUSAND IN EACH GROUP, 1916, 1917 AND 1918

Group	Year	No. of Cities	Total Population	No. of Deaths	Av. Deaths per 100,000
1	1916	9	13,743,746	854	6.2
1	1917	9	14,027,263	774	5.5
1	1918	9	13,809,901	598	4.3
2	1916	10	4,053,281	344	8.5
2	1917	10	4,150,099	329	7.9
2	1918	10	4,372,088	298	6.8
3	1916	10	2,635,983	248	9.4
3	1917	10	2,701,029	173	6.4
3	1918	10	2,773,716	193	6.9
4	1916	14	2,250,991	330	14.7
4	1917	14	2,310,372	307	13.3
4	1918	14	2,449,736	331	13.5
5	1916	17	1,983,918	235	11.8
5	1917	17	2,031,313	229	11.3
5	1918	17	2,053,215	240	11.7
Total....	1916	60	24,667,919	2,011	8.1
Total....	1917	60	25,220,076	1,812	7.2
Total....	1918	60	25,458,656	1,660	6.5

Nine cities reached a rate of 3.0 or less in 1918: Chicago, Lowell, Rochester, Paterson, Seattle, Boston, Cambridge, Los Angeles and Philadelphia.

Again we are encouraged to note the further lowering in the total typhoid rate of the fifty-seven cities whose records are available. Since a large proportion of the males belonging to the age groups especially susceptible to typhoid were in army camps during most of the year, much stress cannot be laid on a slight reduction in typhoid rates. But the facts, so far as they go, indicate a unique condition. It has been the history during previous wars that typhoid has not only prevailed extensively in army camps, but has spread thence to the civilian population. The figures for 1918 indicate at least that no material increase in typhoid has occurred generally in civilian communities. Antityphoid vaccination of the military forces of the United States has not merely protected soldiers in camps, but has probably prevented the spread of the disease throughout the civilian population. This is a great achievement.

TABLE 8.—TOTAL AVERAGE TYPHOID DEATH RATE (1910-1918)

	Total Population (57 Cities*) *Estimated by U. S.* Census Bureau Methods	Typhoid Deaths	Typhoid Death Rate per 100,000
1910	20,996,035	4,114	19.59
1911	21,545,014	3,391	15.74
1912	22,093,993	2,775	12.56

TYPHOID IN AMERICAN CITIES

The seventh annual summary of the typhoid death rates in large American cities appears in this issue of The Journal,[1] and constitutes an encouraging record of sanitary achievement. It might have been anticipated that typhoid would increase in this country during 1918. The absorption of national interest and energy in the war, the absence of thousands of physicians and sanitarians from their accustomed posts, the almost unavoidable interference in many places with normal housing and industrial conditions, the hasty construction of industrial towns in the neighborhood of many cities, and the unprecedented shifting of population, giving the typhoid carriers an opportunity for maximum contact, are all factors that it might have been reasonably supposed would cooperate in producing a general typhoid rate higher than for several years past. It is true that the greatest source of typhoid infection in all previous wars has been removed, namely, the excessive prevalence of typhoid in army camps and its spread from these to the civilian community. Antityphoid inoculation has changed all that. At the same time the other disturbing wartime factors mentioned above are sufficiently important to arouse apprehension as to their effect on typhoid dissemination. But whatever effect they may have had has been more than counterbalanced by the forces tending to bring about a reduction in this disease. Typhoid fever reached a lower ebb in American cities in 1918 than in any other year for which record is available. American health officers deserve great credit for the unremitting work that has made this result possible in the face of great difficulties.

The data gathered by The Journal for the past seven years are of interest and significance in many other ways. One legitimate inference seems to be that typhoid fever in the United States has become to a great extent a rural rather than an urban disease. There is little doubt from the practically unanimous testimony of health officers as well as from other sources of information that a large part of the typhoid infection occurring in American cities originates in rural districts. Death returns especially show that a relatively large proportion of the typhoid deaths in cities is due to infection contracted in other communities. Both patients sick with typhoid and typhoid-contaminated foodstuffs are imported into the city with far greater frequency than they are exported. In a sense this is perhaps the aftermath of long years of city mismanagement of water supplies which for several decades made cities like Philadelphia, Pittsburgh and Chicago distributing centers for typhoid bacilli, and fastened typhoid firmly on the rural regions for miles about. Now that most American cities have practically eliminated the danger of water-borne typhoid for their own citizens, they continue to suffer from typhoid infection shipped in from rural communities in which the seed was originally implanted through the agency of some contaminated city water supply.

At all events, it is fair to conclude that so far at least as many Northern cities are concerned, further improvement in typhoid rates will have to come very largely through improvement in typhoid conditions in the adjoining suburban and rural districts. Especially is this true of the regions from which such important foodstuffs as milk are drawn. Reduction in typhoid in country places will surely be followed by a reduction in the cities to which they are tributary.

To this end it is desirable that more cities should embark, as New York has done, on detailed typhoid studies. In many places typhoid has shrunk to a point at which it is manageable, and each case can be subjected to a more or less careful study. Such observations not only will be of value in detecting local sources of infection, but also will add to the general understanding of typhoid epidemiology. It is to be hoped that many health officials will find it possible to have made and put on record results of inquiries concerning each case of typhoid developing in the municipality. The relative share of urban and rural sources of infection and of other factors can be determined with exactness only in this way.

THE ETIOLOGY OF INFLUENZA

The pandemic of influenza has been the subject of investigation to an unusual extent, not only because of its alarming character and widespread prevalence, but also because it has occurred at a time when great governmental agencies, like the medical departments of armies, were necessarily directed to the study. At the time of the pandemic of 1889-1890, the bacteriologic factors possibly associated with the disease were far from being recognized to the extent that is true at the present time. Pfeiffer's bacillus, the so-called *B. influenzae*, was not described until 1892. Even cursory acquaintance with the literature of influenza since that date cannot fail to indicate the uncertainty that has existed regarding the possible etiologic significance of this micro-organism. The most recent studies undertaken in connection with the outbreaks of influenza during the past year continue to give indications of this uncertainty.[1] Far from regarding the Pfeiffer bacillus as the primary infective agent, many, if not most investigators still insist that influenza is a disease, to quote Kinsella, caused by some as yet undiscovered agent, which produces inflammation of the entire respiratory tract, and effects a very profound lowering of resistance, which is perhaps expressed by the constant and striking leukopenia. Lack of reaction is the most noticeable clinical feature. Under these circumstances, invasion follows by the various bacteria that are capable of becoming pathogenic, although harmless in the normal mouth.

---

[1] Page 997.

It is still too early to marshal the mooted facts into a decisive order. Meanwhile, it can only be helpful to compare the findings regarding influenza which are being arrayed from many quarters as the result of the outbreak of 1918. By contrasting the observations made in diverse places and many lands it should become possible to distinguish the accidental from the omnipresent factors and, at length, formulate more definite theses which may direct further experimental investigations. Accordingly, it is interesting to learn the recently published conclusions of the Kitasato Institute for Infectious Diseases in Tokyo regarding the cause of the influenza that prevailed in Japan last year.[2] The clinical findings seem to agree with those that were obtained in the last pandemic; and according to the Japanese investigators the epidemiologic and clinical data tend to identify the influenza that has prevailed in Japan with the disease recently current in Europe and America.

The bacteriologists of the Kitasato Institute claim to have found *B. influenzae* in almost pure culture in the nasal cavities of patients, while healthy persons do not harbor it in the same degree. Serologic and other laboratory studies lead the Japanese investigators to the conclusion that "this pandemic of the influenza is caused by Pfeiffer's bacillus." They argue that the nature of this organism is such that it affords only a weak immunity to the host; nevertheless, they add, this fact need not disprove its pathogenicity.

The validity of such contributions must remain in abeyance until such rather positive views have been considered in comparison with data gathered from diverse other sources. In a review of their experience with influenza in the Medical Clinic of the Johns Hopkins University, Bloomfield and Harrop[3] also come to the conclusion that epidemic influenza in 1918 is clinically identical with the disease seen in previous pandemics. It is not primarily a local disease of the respiratory tract. They argue that it presents a definite and characteristic clinical picture quite apart from the pulmonary complications; the main features of uncomplicated cases being a constant set of symptoms, characteristic erythema and appearance of the mouth, fever of definite duration, and leukopenia. Bloomfield and Harrop frankly assert, however, that proof is lacking that the Pfeiffer bacillus is the primary cause of uncomplicated influenza. The same conclusion has been reached by Howard[4] of the Johns Hopkins Clinic, who believes with practically all American investigators that *B. influenzae* is merely a secondary invader, though in some cases it may be a frequent cause of terminal bronchopneumonia.

Pritchett and Stillman[5] have found *B. influenzae* present in the mouths of 43 per cent. of normal individuals examined in the personnel of a large hospital. On the other hand, they cultivated the organism from the mouth of 93 per cent. of cases of influenza and bronchopneumonia. This high incidence of the Pfeiffer bacillus in the upper respiratory tract during the epidemic, according to Pritchett and Stillman, is a point in favor of the view that the micro-organism may be of significance in the disease in question. The upshot of all these somewhat comparable findings but conflicting views is that we must defer positive conclusions until more decisive evidence is brought forward.

LIMITING THE USEFULNESS OF THE PUBLIC HEALTH SERVICE

The substantial support given by Congress to the United States Public Health Service during the war encouraged all interested in public health to hope that at last this important branch of the federal government was to be supported in its efforts to meet the urgent demands for a national health service. This hope was all the more justified by the effective work accomplished by the Public Health Service in aiding the nation's war activities. Here, certainly, were numerous convincing demonstrations of what could actually be accomplished by well-planned public health activities carried on through the effective cooperation of federal, state and local health agencies.

In the face of these demonstrations, and despite the fact that the need for health conservation is greater than ever before, it is regrettable to note that Congress, in its plan to place all government departments on a

prewar basis, has deemed it expedient to discontinue or curtail a number of important activities recently developed by the Public Health Service. With the failure of Congress to pass the sundry civil bill, it is true that no final decision on the appropriation for the Public Health Service has yet been reached. It may be profitable, therefore, to examine some items of the program and budget prepared by the Public Health Service and compare this with the recommendations made by the Committee on Appropriations of the House of Representatives.

The reductions proposed by the committee relate chiefly to the items on field investigations of public health, interstate quarantine service, studies of rural sanitation and venereal diseases, and embrace both research and administrative work. For instance, the request for field investigations of public health—which embraces much of the research work of the service—was cut from $1,050,000 to $300,000. Under the appropriation requested, the bureau proposed to meet at least some of its responsibilities in the field of child hygiene ($150,000) by studying important problems relating to infant mortality, malnutrition and school hygiene, and by making demonstrations in this field in cooperation with state and local health authorities. The sum of $100,000 was asked for to improve the system of collecting morbidity reports by stationing a statistical clerk in each state and providing a central office for the tabulation and publication of this material. Half a million dollars was assigned to the very important field of industrial hygiene, a third of the sum for research on such matters as industrial air conditions, the employment of women in industry, industrial poisons in the dye industry, industrial fatigue and illumination, the rest for field investigations in cooperation with the Department of Labor, and state departments of health and of labor. Finally, the sum of $300,000 was to be utilized to study infectious diseases in man. When one considers the enormous havoc still wrought by diseases ordinarily considered preventable, as tuberculosis, pneumonia and malaria, this sum certainly constitutes a reasonable request. Yet in spite of the urgency of these investigations, the committee cut the estimate 70 per cent.

The requests made by the Public Health Service under the other heads suffered a similar reduction. For interstate quarantine, in place of $850,000 requested only $25,000 was recommended; for rural sanitation, in place of $500,000, only $50,000, and for venereal diseases, in place of $1,085,000, only $200,000 was recommended.

Among the items of the estimate that suffered severely was that for the control of biologic products, the appropriation for which was reduced from $100,000 to $35,000. The result of this will be that research in the field of serums and vaccines and similar products will be curtailed in a most serious manner. This particular subject is second to none in importance to the medical profession, and it will be most unfortunate if the activities of the services in this respect must be reduced.

It is not believed that the radical reductions recommended by the Committee on Appropriations reflect any antagonism on the part of Congress toward the Public Health Service. They seem rather to represent only the general policy of retrenchment which needs must be adopted in order to return the country to normal peace conditions. It is most unfortunate, however, that the attempt is apparently being made to effect horizontal reductions rather than to consider each activity in relation to the postwar needs of the country. From the latter standpoint the activities of the Public Health Service surely demand expansion and development rather than curtailment.

As a new sundry civil bill will soon be considered by the new Congress, the time is most opportune for physicians to express their interest in public health by urging favorable action by Congress on the appropriation requested for the Public Health Service. That this will be utilized to good advantage may be seen by studying the excellent program prepared by the Public Health Service, printed on page 1023 of this issue.

DEFECTIVE NUTRITION OF CHILDREN IN WAR-STRICKEN EUROPE

We have taken occasion at various times to point out some of the important practical consequences of the more recently acquired information regarding the food requirements of the human body in childhood. Contrary to the older assumptions, whereby the needs of the growing child for food fuel were expressed in proportionate fractions of the energy requirement of the adult, the modern nutrition studies, in this country in particular, have demonstrated the unexpectedly higher basal metabolism of childhood. If it is true, as Lusk[1] has maintained, that many cases of reported chronic malnutrition of infants are in reality due to persistent undernutrition, carried out in ignorance of the proper amount of food required by the child, a comparable ignorance applies to the dietary of later childhood years. It cannot be reiterated too often, until the knowledge has been firmly established where it is most needed, that the basal requirement of boys is, as Du Bois has shown, 25 per cent. greater than that of the adult. A growing, vigorous youth may consequently not be satisfied with a daily intake of 3,000 calories, which might be ample for the nutrition of his parent.

Throughout the period of stress in respect to available food during the war, even at a time when patriotism and self-preservation called for the utmost conservation of our food resources, the United States Food Administration has never overlooked these higher food requirements of the American youth. The avoidance of waste has never been translated into a stinting of the proportionately higher dietary allowance especially called for in childhood. The American food conservation propaganda has been wisely guided by experts in the science of nutrition rather than by mere political appointees. Consequently comparatively little physiologic detriment seems to have been experienced.

---

[1] Lusk, Graham: The Fundamental Basis of Nutrition, 1914, p. 15.

How other countries have fared remains to be learned when the statistics and other forms of evidence become available through the renewed scientific intercourse after war conditions. An exceptionally interesting indication of what failure to realize the fundamentals of nutrition may entail during the years of childhood has been brought to light in a recently published account from one of the large orphanages of Berlin. Fuhge[2] has made accurate measurements of the food intake and metabolic balance of a group of children ranging from 6 to 14 years of age during the third year of the war, when food conditions were evidently becoming serious. The total calory intake as well as the proportion of protein ingested were evidently small, so that vigorous exercise sometimes entailed a notable loss of body tissue. The deficit in the diet was attributable in considerable degree to the diminution of fat allowed.

The detailed statistics of such investigations are of interest to the specialist alone. Of more widespread significance is the evidently retarded growth of the children thus examined. The failure to provide adequately for the nutrition of childhood in the Central Empires is similarly indicated in reports published from Prague during the past year.[3] The appearance of infantile scorbutus seems to have been one of the varied consequences falling in the wake of inappropriate nutrition. Unless marked improvement in the dietary possibilities, and particularly a more intelligent appreciation (even in the historic home of the science of nutrition) of the requirements of childhood are soon attained, the consequences to large numbers of developing individuals may be most unfortunate. As Mrs. Rose[4] has admirably expressed the situation: one year of good feeding at the beginning of life is more important than ten years after 40, and a baby's needs are not to be judged by an adult's inclinations. Feeding must be a matter of principle and not of impulse, and the reward will be partly in the present —much more in the future. We should profit by the lessons of European misfortune. Perhaps we can help by precepts as well as by contributions to avert further disaster among the sorely stricken inhabitants of the invaded and other afflicted lands.

Current Comment

IS A CHILD'S LIFE WORTH SIX DOLLARS?

How much does it cost to prevent deaths from diphtheria? The Ohio *Public Health Journal* for February gives the experience of the City of Salem, Ohio, for twenty years. During the ten years from 1890 to 1899 this town of about 10,000 inhabitants had 162 cases of diphtheria, with forty-eight deaths, or 30 per cent. In 1900 the city health authorities began furnishing free antitoxin for all cases of diphtheria. In the ten years from 1900 to 1909 there were 126 cases, with only one death — a case in which antitoxin was not administered until the third day. Had the percentage of fatalities been as high during the second decade as during the first, Salem would have had thirty-seven deaths from diphtheria in that time. The free antitoxin furnished for the ten years cost the city approximately $220, or an average of $6 per life. Any community desiring to know how much it would cost to save a child's life from diphtheria can ascertain this by multiplying the annual number of diphtheria cases by the cost of 5,000 units of antitoxin, and dividing the result by the number of deaths from diphtheria each year.

FALLACIES IN THE DISCUSSION OF SOCIAL INSURANCE

In the present discussion of social insurance in this country, as in England ten years ago, it seems impossible for either its advocates or its opponents to avoid extreme and partizan statements. Arguments on both sides are characterized by sweeping generalizations and unwarranted deductions, which too often are accepted by the reader because they are made by some well known authority. An illustration of this tendency is to be found in an editorial in the *New Republic,* March 22. After stating that "neither Republican nor Democratic leaders can afford to compromise" on the health insurance bill now before the New York legislature, the editorial continues: "Organized labor has unanimously placed health insurance first among its immediate legislative demands." This statement is incorrect. If the editor had said, "Organized labor *in New York State* has unanimously placed health insurance first among its immediate legislative demands," his statement would have been correct. The New York Federation of Labor has indorsed health insurance, as have a few other state federations. Enumerating the forces behind the measure, the *New Republic* says: "An impressive array of civic societies, far-sighted employers and physicians have come to the support of the bill." No "impressive array" of physicians has as yet supported any health insurance measure in any state. The editorial continues: "Congress adjourned without taking any action. The states must step into the breach — above all the pivotal state of New York." No measure providing for national health insurance has ever been presented to Congress, nor could Congress take any action on this subject. It is essentially, a matter that comes under state jurisdiction. New York may be a "pivotal state" in the political field, but it is no more pivotal from an industrial or economic standpoint than is Massachusetts, Pennsylvania, Ohio or Illinois. The editorial concludes: "The health insurance bill is the most important measure now before the legislators and the people of New York State. It should be passed without compromise, evasion or delay." It should if it is the best bill that can be devised; otherwise, it should not. If in the New York bill the interests of employees, employers, physicians and the state were properly safeguarded, then the statement of the *New Republic* might be accepted. But in the present state of knowledge on this question, any bill is an experiment. Probably before its passage, certainly before its administration is possible, a considerable amount of compromise will be necessary. Delay at present is not only unavoidable but desirable. No state has as yet passed any health insurance measure. The progress of the first state that does will be carefully watched. If delay affords an opportunity for careful consideration of the many phases of the bill, exhaustive discussion of the details, and a patient hearing to all interested parties, then the delay will be well worth while. Probably in no field of legislative action today is so great caution and deliberation advisable as in the field of social insurance. The editorial in the *New Republic* is a fair sample of the hasty and often misleading generalizations that are appearing on this subject. It is more than ever necessary that physicians keep cool heads and clear judgment, and refuse to allow their attention to be diverted from the essential principles involved in these proposed measures.

THE VICTORY MEETING

From the reports received from the Local Committee on Arrangements, the attendance at the annual session of the American Medical Association in Atlantic City next June—the Victory Meeting—will be unusually large. It therefore behooves those who will attend the meeting to make hotel reservations early. This suggestion should not be understood to mean that hotel accommodations will *not* be available, but that hotel accommodations in the hotels on the beach front — the Boardwalk — may be difficult to secure. Attention is called to this matter solely for the purpose of urging those who particularly desire to be on the beach front to make their reservations early. Off the Boardwalk — up in the town — there are a number of excellent hotels. Two weeks ago, a list[1] of the hotel headquarters of the various sections was published in The Journal. An extended list of the Atlantic City hotels announcing rates and capacity is being prepared for the "Victory Meeting Number" of The Journal. In making reservations, the hotels should be addressed directly, or in case difficulties are encountered in obtaining satisfactory accommodations, the assistance of the chairman of the Local Hotel Committee, Dr. David B. Allman, or of the chairman of the Local Committee on Arrangements, Dr. Emery Marvel, may be requested by addressing them at Atlantic City.
